Past studies. Specific social, psychological, and clinical psychiatric studies have broadened and extended our ideas about etiology and about the psychopathology of the entity. Although it is difficult to assess the relative contributions of the many individuals who have contributed to our growing understanding of the psychopathology of delinquency, Aichhorn clearly made the significant observations that made it possible for psychiatry to look beyond purely medical, biological, and inherited constitutional ideas for explanations. In his book, *Wayward Youth*, he reported his observations about the wide variety of personality types that he encountered and he described in vivid detail his clinical efforts to establish meaningful therapeutic relationships with such children. Eisler's *Searchlights on Delinquency* brought many of Aichhorn's ideas into sharp focus, including his observations of the connection between gross criminal behavior in the parent and delinquent behavior in the child.

The essential idea in the theories about delinquency in the early 1950's was that some defect or distortion in the conscience was present. Most experts thought

that this abnormality was caused by a constitutional inability to develop an inner control system, by identification with a pathological parent or parent figure, by severe and cruel social and emotionally traumatic experiences in a particular social or cultural group, or by some combination of these factors. Healy and Bronner, pioneers in the field, thought that parental coldness was the major factor; however, Szurek and Johnson demonstrated in their clinical work the high probability of the existence of specific defects in the conscience.

The Johnson-Szurek thesis is that the antisocial behavior in the child is encouraged unconsciously by a parent or parents who participate in the process, vicariously gain pleasure in the child's deeds, and subtly carry out their own unconscious hostile and destructive feelings toward the child. As an illustration, a mother in a car pool laughingly admonished her son, who was biting another 5-year-old boy on his arm, by saying, "Johnny, don't bite him *so hard*." The mother remained quiet and detached when the other children came to the victim's rescue and began to pound Johnny quite actively. As our knowledge about language (linguistics) and nonverbal behavior (kinesics) becomes more and more precise, it is evident that the child is learning constantly many of the beliefs, customs, and models of behavior he sees and experiences in his relationship with parents and peers.

Studies on pathological development have been paralleled by increasingly sophisticated studies on the child's moral development, as illustrated by the work of Woolf on moral development and the longitudinal personality development studies of Benjamin and others. We now recognize the importance of the nature and consistency of the mothering experience and later emotional experiences on the emerging character structure of the child.

Kaufman has made a number of important observations about the association between loss of a significant love object by illness, abandonment, or death and delinquency. The child develops grief and depression and continues a restless, angry search for the lost object, with resulting narcissistic and delinquent behavior.

Redl has made further contributions to our understanding of the psychopathology of antisocial behavior, especially in regard to his observation about the existence of unusual ego strengths in individuals with severe character defects. He suggested that, in the development of an adaptive pattern, certain personality functions become hypertrophic in order to compensate for the existing defect or deficiencies in character structure.

Current ideas. Current ideas about the psychopathology in delinquent behavior usually contain these four elements: (1) The child feels significant emotional deprivation and strongly resents it. (2) The child cannot establish his own range of skills because his parents have not set the limits for him.

(3) The parents, especially the mother, are very often overstimulating and inconsistent in their attitudes toward the child. (4) The child's behavior usually represents a vicarious source of pleasure and gratification for a parent and is often an expression of the parent's unconscious hostility toward the child, as the behavior is either overtly or covertly self-destructive to the child.

Clinical Features

Antisocial and dyssocial reaction types of behavior present a wide variety of clinical pictures to the psychiatrist. In the absence of confusion due to toxic or organic factors, the child is usually superficially tense when he is brought to a psychiatrist by a parent, court worker, or social worker. He is often sullen, defiant, and flippant; he answers questions briefly and in a matter of fact tone, uses denial extensively, and tends to minimize the reasons for the referral. Usually the child is reluctant to share inner emotional experiences, feelings, day-dreams, jokes, favorite books or television programs. He frequently projects personal difficulties onto a parent, sibling, or peer and almost always minimizes his involvement in any meaningful personal relationship. The usual and expected guilt feelings are frequently not present or are merely glossed over quickly without much evidence of personal discomfort.

Differential Diagnosis

Differential diagnosis requires a thorough and careful evaluation of the biological, psychological, and social factors that may contribute to the development of the maladaptive behavior. A detailed and accurate history, physical and neurological examinations, and psychological and various laboratory tests are required to evaluate brain damage, mental retardation, and similar causes of the behavior. Direct observation of the child in an interview and skilled evaluation of the parents and perhaps of the parents and child together may give valuable clues to the possibility of a conscience defect, affect deprivation, major and significant loss of a loved person, or a major connection between the parents' behavior and the child's symptoms of an antisocial nature.

An adequate differential diagnostic statement should make some attempt to define the interaction between the biological, psychological, and sociocultural forces and attempt to assess the possible precipitating causes and contributing factors to the behavior.

An 8-year-old girl was truant from school while her parents were away from home for 2 weeks. The girl was bright-normal intellectually, in good physical health, very closely attached to her father and her mother. The major past historical event was the death of her maternal grandmother, who was quite close to the child and to the mother, so that the child experienced a dual loss—of the grandmother and of the mother, who was depressed. The parents' trip was the first significant absence of

the mother from the girl since the grandmother's death. The truancy seemed to be a cry to the mother, "Return home and take care of me." Probably, it also had oedipal fantasy meanings.

In the biological areas, the claims and statements about the significance and importance of abnormal electroencephalographic findings remain controversial and widely debated in professional circles—for example, the association between abnormal EEG clinical findings of the 14 per second and 6 per second cycle pattern and outbursts of uncontrolled aggression.

Prognosis

The prognosis in treating antisocial and dyssocial reactions is poor to fair. Obviously, the prognosis is much better if the behavior pattern emerges for the first time after the child starts school, if it is recognized promptly, if proper and adequate intervention occurs, and if both the child and the parents are motivated to a genuine exploration of the underlying sources of the undesirable behavior.

The work of the Gluecks offers much hope, as they have pioneered the efforts to identify high risk populations of predelinquents and to study the personality characteristics of children who seem to move on to a specific, repetitive type of delinquent behavior in later years. The sociological factors in delinquency have also been receiving increasing attention and knowledge about them may well contribute to our understanding and management of the delinquent.

Management

The management of delinquency should be considered by general physicians and by psychiatrists in two areas—direct treatment and prevention. Treatment involves a thorough diagnostic study and a definition of the extent and nature of the clinical problem. In most instances, it is necessary to work with the child and with the parents in a collaborative team approach, as advocated by Szurek, Kaufman, and many other writers. The individual therapy usually has some special features that vary considerably from most child psychotherapy.

1. The presence of early childhood defects or distortions makes it necessary for the therapist to present himself consistently as a warm, understanding person.

2. There should be a strong reality orientation in the collaborative process, with specific emphasis on requiring parents to set consistent and realistic limits on the child's behavior.

3. There should be recognition of the high probability that the parents may not want to give up their vicarious and usually unconscious pleasure in the child's behavior.

4. The specific therapeutic maneuvers called deceiving the deceiver, first advocated by Aichhorn and later elaborated on by Hoffer and others, may be useful if employed by a skilled therapist.

Residential treatment. In many instances it is necessary to treat the delinquent in some type of residential institution to break the ties with the stimulative and destructive parent or to compensate in part for the absent or unavailable parental figure. Here, the multidimensional complexity of the dynamics of delinquency must be dealt with by an equally complex set of institutional factors. The personnel must somehow provide the food, clothing, shelter, health care, education, and opportunity for new learning through individual and group psychotherapy and thus try through the experiences in group living to give the child new and corrective emotional growth opportunities. Aichhorn's ideas about residential therapy have been reformulated by Redl and many others.

The treatment focus seems to be shifting away from punishment and retaliation to a greater focus on causes of problems of social isolation and social distance. The residential group attempts to focus on children with weak and inadequate personality resources and to provide them with some nurture to compensate for the individual child's feeling of being unloved earlier in his life.

Psychotherapy. Whether in individual, group, or residential settings, it seems clear that most workers agree with Redl's idea that therapeutic work with delinquents, especially adolescents, requires much activity by the therapist. He suggests that it is important to keep the patient talking, to keep him active, to keep him reality-oriented as much as possible, to try to get enough of a relationship with the therapist so that the child can inhibit his tendency to act out impulses and to develop instead feelings of guilt, shame, remorse—that is, more classical neurotic personal feelings.

Noshpitz has suggested several specific principles in psychotherapy with severe delinquents. First, the therapist should not encourage the emergence of instinctual behavior. ("You want to show me what you want to do; I want you to tell me instead.") Second, the therapist should recognize the child's fear of loss of control over his own impulses. Third, the therapist should recognize the child's inevitable wish for consistent limit setting.

Drugs. There is clinical evidence of better control of epilepsy and other behavioral disorders by new pharmacological anticonvulsants and tranquilizers. In the area of individual treatment, the possibility of using antidepressants in conjunction with specific brief abreactive psychotherapies, the use of phenothiazine drugs in the management of childhood psychoses, and the judicious use of milder tranquilizers and stimulants to aid in the management of hyperkinetic and impulse-ridden children seems promising. It is hoped that the current psychopharmacological revolution will have the same effect on psychiatric treatment as anesthesia did on surgery, in that it may permit clinicians to utilize drugs more actively

in children to interrupt maladaptive and faulty patterns of behavior, to facilitate the development of new and healthier patterns.

The Future

It seems reasonable to expect—with our rapidly urbanizing and industrializing country, the impact of the great increases in population in the world, the increasing facility of our radio and television communication media, and the gradual liberalization of our sexual and social morality—that the problems of dyssocial and antisocial behavioral patterns will remain important clinical matters for behavioral scientists in the future.

Physicians and psychiatrists, working in close collaboration with psychologists, sociologists, social workers, educators, judges, and many other personnel in the newly developing field of community mental health, must contribute their knowledge and skill in the evaluation, diagnosis, treatment, and management of delinquency in the years ahead. It is hoped that new therapeutic developments from psychologists and learning theorists will emerge, especially ideas about the use of operant conditioning. Group therapy approaches may be refined, which should prove to be useful with acute and less severe types of delinquency.

Suggested Cross References

Sociocultural determinants of juvenile delinquency are presented in detail in Section 41.5. Antisocial and dyssocial reactions are also discussed in Section 26.1 in Area F, which deals with the psychiatric disorders of adults.

41.5 SOCIOLOGICAL ASPECTS OF JUVENILE DELINQUENCY

MARCIA K. FREEDMAN, Ph.D.

Cohen has formulated the distinction between psychological and sociological approaches to crime by contrasting the psychological question "How do people become the kind of individuals who commit criminal acts?" with the sociological question "What is it about the structure of social systems that determines the kinds of criminal acts that occur in these systems and the way in which such acts are distributed within the systems?" Keeping this distinction in mind, it becomes clear that the task of theory building in sociology is enormous, in keeping with the size of the social system, which forms the basic unit of analysis. Sociological theories are, expectedly, far from parsimonious or elegant explanations; even so, clinicians may find them of use in patient management, since they help to illuminate the situations in which delinquent acts originate.

Definition

The term "delinquency" suffers from looseness of definition. It may include all deviant behavior among the young, ranging from actions that are classed as criminal among adults, such as assault and robbery, to offenses that are strictly age-related, such as truancy, driving, drinking, and sexual activities. Furthermore, these "deviant" behaviors are punished differently in different communities and among different social classes. Explanations for given occurrences, therefore, tend to falter when applied to another set of circumstances.

Epidemiology

Delinquency has steadily increased in almost every country in the world. It appears to be a feature of modern industrial society, in which rapid technological change, high rates of mobility, and the conditions of urban life result in social instability, what sociolo-

gists refer to as *anomie*, or normlessness. The concept of *anomie*, however, is insufficient to account for the various forms of deviance both between and within cultures.

Etiology

Bordua, whose review of the subject is an excellent introduction, distinguishes two major approaches in theoretical attempts to explain delinquency on a sociological level—one that attributes delinquency and other manifestations of deviance to the lack of effective social controls, and the other that seeks to establish motivation for delinquent acts not in psychological terms but in cultural and subcultural terms.

Lack of social controls. Theories developed prior to World War II tended to reflect the first approach. Thus, Shaw and McKay's area approach was based in part on types of land use in big cities and the effects of immigration and urbanization on heterogeneous population groups. The resulting instability—that is, the lack of effective social control, particularly in the inner city areas—was conducive to the formation of delinquent groups with their own codes of behavior, in which individual boys might find personal gratifications otherwise unavailable to them.

In such theories, the problem of motivation is not a serious consideration. It is assumed that motivation derives from participation in a specific social setting where the absence of controls and mutual support in the group are sufficient to perpetuate delinquent behavior. These early theories were subject to two major critical objections. First, if they accounted for the delinquent as an individual who came under the influence of a group, they failed to account for the origin of delinquent patterns. Second, they were limited in their application to disorganized urban areas.

Subcultures. The second approach distinguished by Bordua arose in an effort to account both for motivation and for the origin of specific delinquent patterns. These patterns became theoretically formalized in the 1950's as subcultures. Cohen postulated the formation of delinquent subcultures as a response to status deprivation. Lower class boys who cannot measure up to middle class standards of success tend to seek a collective solution to their lack of social esteem and self-esteem through interaction with others similarly situated. The resulting delinquent subculture turns middle class norms upside down and tends, therefore, to be malicious, hedonistic, and utilitarian. In effect, the subculture protects its members from their own recognition of the validity of middle class judgment.

Cloward and Ohlin accounted for the formation of delinquent subcultures in a different way, which rests in part on Merton's theory of the origin of *anomie* itself. In this formulation, deviant behavior, of which delinquency is one form, results when some groups in the society do not have access to the means necessary

to achieve cultural goals. Cloward and Ohlin's position is that the unjust distribution of opportunity, particularly with respect to income, drives lower class adolescents either into the *illegitimate* opportunity structure (organized crime) or into alternate groups characterized by combat (gangs) or by retreatist behavior (drug use subcultures).

Miller, whose work has focused specifically on gang delinquency, sees the origin of delinquent behavior in a distinctly lower class culture, rather than as any kind of reaction formation to middle class culture or alienation from the dominant norms. Lower class adolescents are simply reflecting the focal concerns of their milieu—trouble, toughness, smartness, excitement, fate, and autonomy.

Matza, taking quite a different tack, views delinquency from the perspective of classical criminology. In the legal context with which he is concerned, the most relevant factors are injustice and its consequences in indeterminate punishments, labeling, and resentment. In his view, delinquents are not necessarily committed to deviant or to conventional values. The beliefs that constitute the subculture of delinquency serve to permit rather than to compel delinquent acts. Their function is to neutralize the moral precepts of the law, and the result is drift between criminal and conventional action, with delinquent acts occurring only sporadically. Matza, in effect, reintroduced the lack of social controls as an important element in delinquency (albeit in more sophisticated form). The mere absence of controls does not necessarily result in delinquent behavior, but their absence provides the setting for activating the will to crime. "The conception of will," he said, "need not carry the whole burden of explanation, as it came close to doing in classical criminology. Instead, it may represent the missing element needed in social control theory by which the potential for delinquency implicit in drift can be realized."

Value of Sociological Approach

The theories mentioned here, as well as other attempts to build total or partial explanations for delinquency, are far more complex than this presentation may imply. At the risk of oversimplifying, however, it is worth pointing out certain of the shared strengths and weaknesses of sociological approaches to delinquency. By and large, as Bordua pointed out, they are incapable of empirical verification. Their theoretical constructs are highly abstract, and it is often difficult to specify the linkages between these abstractions and the particular acts that are said to flow from them.

Effects of institutions. The usefulness of sociological theories lies in their emphasis on the effects of institutions and in their stress on the collective nature of delinquency. It is well recognized, for example, that the occurrence of delinquency is often correlated with school failure. Failure in

school is related not only to academic interest or ability but also to the successful negotiation of the school as a social system. There are critics like Friedenberg who deplore the school as a social system and who stress its purely custodial, antiexpressive controls. Nevertheless, those adolescents who succeed in school are generally those who are able to use the school as the locus of their peer group life as well as the setting for acquiring information and knowledge. To do this successfully generally requires acceptance of the norms and standards of the adults in the system.

Stinchcombe's study of expressive alienation among high school students led him to conclude that the open flouting of school authority (rebellion) occurs as a result of one or both of the following conditions: (1) when a student's future status does not depend on current performance, that is, among boys with limited academic ability or interest who see school as irrelevant to the low status jobs they expect to hold; (2) when students, failing to accept the school's formal culture, in which they have inferior status, seek to usurp adult symbols. According to Stinchcombe, actual rebellion is most likely to occur among those school failures who are under the most pressure to succeed.

If an adolescent cannot or will not identify with the school, it does not necessarily follow that his only option is delinquent or deviant behavior. Nevertheless, the increase in years of schooling in the United States has had the effect of limiting alternatives for work. The consequent lengthening of the period of dependency is one aspect, but not the only one, of the social system that creates the conditions for delinquency.

Adolescent groups. In stressing collective behavior, sociological theories serve to focus on the adolescent group—what Matza calls the "situation of company"—which serves both as the locus of the action and as the source of mutual support. It has been commonplace, for example, to view the delinquent acts of middle class, suburban youths as individual aberrations of psychic origin. Recent reports, however, make it clear that, although the individual emotionally disturbed adolescent acts out in both the city and the suburb, a good deal of behavior that disturbs both kinds of communities takes place in groups.

The stress on situational factors also serves as a caution against assuming that all delinquent acts are the consequence of a deep commitment to delinquency, whether psychologically or sociologically induced. The fact that most delinquency and crime rates decline sharply with advancing age argues against such commitment. Furthermore, insofar as psychic disturbance is an element in delinquency, it may also be an element in other kinds of deviant, as well as in conforming, behaviors.

Typologies. One promising new direction in the treatment of delinquency is the attempt to build typologies and classifications that combine demo-

graphic, cultural, and psychological factors. Types of delinquent behaviors and types of delinquents may then be more readily accounted for. In effect, some of the existing theories have set about this task from the opposite end—by first postulating the existence of one or more types and then attempting to explain them. It seems likely that these explanations may prove valuable, if not for the whole range of delinquent behaviors, at least for single types.

Suggested Cross References

Clinical aspects of juvenile delinquency are discussed in Section 41.4. For additional information regarding social and cultural determinants of psychiatric disorders, see Sections 4.2 and 4.1, respectively, in Area B, on the basic behavioral sciences.

41.6 SOCIOPATHIC PERSONALITY DISORDERS. II: SEXUAL DEVIATIONS

HENRY H. WORK, M.D.

Definition

Despite the central position of sex in the developmental processes of the child, it is not common for younger children to be referred for psychiatric care because of a problem specifically related to sexuality. This becomes less true as the child increases in age. With adolescence, abnormal gratifications of sexual impulses increasingly cause parents to seek help. Even then, however, many of the symptoms that so-

ciety feels are inappropriate in a sexual sense are more likely to receive attention through legal channels than through medical channels. This is particularly true of girls. The bulk of delinquent actions involving girls in most parts of this country consists of sexual activity of one sort or another.

Physicians may or may not regard such activity as abnormal. Normal sexual behavior is defined by society both as a general phenomenon and in relation to varying geographic customs. Since the etiology of deviant sexual behavior is not fully known, it becomes a problem wherever it exceeds what is accepted as a norm for any particular community. In considering sexual problems, one must realize that sex is only one role in the gamut of human behavior. However, so crucial are the interpersonal activities connected with sex that deviant behavior in this role becomes of greater importance than many other activities of life.

Sexual deviation in children represents a greater degree of immaturity of emotional development than does similar pathology in adults. In another frame of reference, it can be considered an unusual continuation of the normal activity of one of the early periods of development. Since society decides whether sex shall be openly exhibited or carried on within the confines of the home, the outward aspects of sexuality must relate to the demands of society. When individual expressions of sex exceed community prohibitions, they may be considered sexual deviations.

Epidemiology

A number of sexual activities, such as masturbation, are extremely widespread in society. The fact that such expressions of sexual activity are universal does not mean that they are necessarily normal. In normal development the child goes through periods of genital sexual satisfaction, which include early masturbation, homosexual attachment to peers, and finally heterosexual strivings leading toward intercourse with a mature partner of the opposite sex. Such normal development does not always proceed smoothly. If the child during his normal development subdues all his sexual impulses, the public is not particularly concerned. In this sense then, asceticism, with its complete inhibition of sexual drives, evokes only public apathy. However, when the child is overstimulated and develops an abnormal sexual appetite in any direction, heterosexual or homosexual, the promiscuity that evolves arouses public concern. The same is true of any of the deviations of sexual patterns occurring at any point during childhood.

Within this society there is a wide variety of sexual expectations and permissions. In general, the middle class sets the moral tone and has the most organized sexual codes. These consider the girl the more passive individual and are more likely to expect greater sexual activity on the part of the male. Some evidence suggests that these patterns are changing in the direction of earlier and more open expressions of heterosexual

activity. Overt homosexuality has been fairly consistently frowned on in the American culture, especially by those parts of society that have only tolerated demonstrations of overt heterosexuality. Pathology, therefore, is brought to medical attention when it violates the mores of that segment of society in which it occurs.

The epidemiology of sexual abnormalities can also be understood as part of the relationship of the child to the parent as the child goes through the normal stages of development. Particularly important are those aspects of parent-child relations that seem to be stimulatory of sex activity. In certain classes of society, such stimulating activity may be quite common. Where parents and children live closely together, intercourse and other sexual activities are more commonly seen by the children, and in some instances there may be overt attempts on the part of the parents to stimulate sexual activity on the part of the children. Of increasing concern is the number of mothers who live alone with their sons, and who in many unconscious aspects of living with them serve as stimulants to the child's developing sexuality. The practice of mothers' sleeping with their sons may stir up an abnormal kind of sexual activity, without either being consciously aware of the distortion. This rouses up anxiety in the boy, which is often met by acting out and by increased amounts of sexual activity as he goes into his adolescence.

One etiological approach to homosexuality suggests that the condition is often noted in families with a dominating mother and a hostile or passive father who provides a poor masculine example. The boy, therefore, is stimulated by an excess of maternal or feminine contact during his early years and thus develops an abnormal concept of his own identity and his own sexual role.

Excessive inhibition of the childhood manifestations of sexuality also plays a role in the development of symptoms. The expressions of parental taboos often carry a message of intrigue and salacious delight, which serves to stir up the child. The value of the activity is increased by being forbidden. The development of specific deviations in these instances may relate to the emphasis used in suppressing the particular acts of the child. Coupled with more general anxieties, a mode of symptomatic expression is clearly demonstrated.

Clinical Aspects

The sexual deviations one sees in children are not grossly different from those seen in adults. Abnormal sexual patterns serve as an outlet for anxiety. Characteristically, the sexual pattern of deviate children includes a repetitive quality and a compulsive sort of activity to relieve the tension. The bulk of deviate sexual patterns in childhood appear to have a neurotic base. In many instances, the child's sexual activity represents an unconscious wish of the parents.

The forms of sexual concern brought to the attention of the physician are similar to those described in adults. There is an important difference, however, since children are brought to a physician for help with the

complaints of a sexual nature being made by parents. When such children are brought in, the history is often very lurid and vivid. The parents complain of excess sexuality of an autoerotic nature, such as masturbation, or of a variety of homosexual and heterosexual contacts.

Especially when the history includes autoerotic complaints, one senses a gross exaggeration and fear on the part of the parents. The presenting parent, in most instances, is the mother. Characteristically, she presents the child with the statement that he masturbates frequently and that she is excessively concerned and feels that something drastic needs to be done. She often points out that she has herself made violent efforts to cut down on his masturbation by sewing up his pockets, threatening him, etc. It is often apparent in such cases that the child, although not innocent, is at least less involved in the symptomatic process than the mother making the complaints.

Similar stories continue to be true for children up through adolescence. At this time, stories of excessive heterosexuality are more common. It is important, therefore, to get an accurate history, one that reflects what is really going on in the child as opposed to the picture presented by the family. Similar stories are sometimes offered by teachers and others, who exaggerate minimal sexual activities and blow them up into major psychiatric disasters. Any child who begins to demonstrate sexual problems causes concern in those around him, and some of this concern reflects adult anxieties more than it does childhood practices.

In considering the sexual deviations of childhood, one must realize that overt sexual activity frequently accompanies psychotic conditions in childhood. In the regressive phenomena that are manifest in childhood schizophrenia, there may be sexual displays, obscene language, exhibitionism, etc. It is important to separate out these manifestations of an underlying psychotic condition from those neurotic situations wherein sexuality has become the primary symptom.

Masturbation. Masturbatory activities begin extremely early in life. Children during the 2nd year are frequently observed playing with their genitalia and obtaining satisfaction from it. Parents are particularly prone to move in very quickly when any signs of genital autoerotic stimulation are seen. A certain number of children continue to masturbate more actively than others. Such masturbation is nearly always associated with some form of stimulating expression, conscious or unconscious, on the part of the parents. Masturbation occurs in small children as part of the psychotic process; however, during latency a certain number of children demonstrate more overt masturbation than others, and this causes considerable concern to teachers and other adults. At times, masturbation becomes part of an acting out behavior on the part of small gangs, particularly among boys. It is frequently associated with other evidences of sexual deviation, such as oral copulation. With the onset of

adolescence, masturbation becomes a more overt sexual activity because of the end point of satisfaction that is then obtained. It is normal for younger boys to be taught about masturbation at this age.

Important in considering children who masturbate excessively is the guilt that is associated with it. This guilt is more or less implanted in our culture, although there is some evidence that it seems to be decreasing. Masturbation is a normal form of behavior and is regarded as pathological primarily because it may become excessive and because of the anxiety and concern that is related to it on the part of the child. Some younger children become excessively involved with masturbation and seem to have a compulsion to carry it on. These children usually demonstrate that they are masturbating because of anxiety. They freely talk about their inability to stop masturbating because of the pressure to carry it on. Such children are nearly always involved with other sexual activities at the same time.

Homosexuality. Since nongenital, same sex peer relations are a normal part of development, it is not always easy to determine when the child is deviating from the customary pattern. With the onset of adolescence, there is a stirring up of the relationships of children of both sexes, both to their own sex and to the opposite sex. The psychiatrist, then, sees homosexuality as a part of normal development and as a part of a confusion in the older child about his sexual identity. Whenever children are placed together in institutions, such as schools and residential homes, there is a stirring up of homosexual activity, manifested both by overt sexual relations and by the fears that children have about such relations.

Some children, however, demonstrate very early in life that they are uncomfortable with the opposite sex and have confused gender identifications. Evidence of such confusion is obvious in the boy who seems grossly attached to his mother and takes on a feminine type of habitus. He prefers to express his feminine relationship with individuals of his own sex and is concerned about relationships between sexes; however, he himself is more feminine than masculine in his identity. Although it is normal for the small boy to be dependent on his mother and cling to her, to continue this process beyond the normal oedipal resolution is obviously a sign of pathology.

Transvestitism. Although not necessarily related to homosexuality, transvestitism is a developmental phenomenon wherein the child is in a sense deprived of normal gender identity. Transvestitism in children is most commonly associated with a pathological relationship between the parent and the child of the opposite sex. A boy, for example, may be both consciously and unconsciously reared as a girl. He is placed in girls' clothing early and is offered only those satisfactions that are normal to the feminine sex. The boy, therefore, grows up with an exaggerated and deviant understanding of his own sexual role and appears to prefer, after a period of time, the habitus and activities of a

girl. Such deviate developmental phenomena appear to be increasing, but they are also subject to prevention if one interferes early. The full meaning of transvestitism is currently under investigation, but it is not as yet clarified.

Abnormal relations. Children are both the objects and the subjects of abnormal sexual relations. Unfortunately, many children are used by adults for their own sexual pleasure. Children are also encouraged, at times, to have relations with inanimate objects and lower animals. Such stimulation may in some instances be a form of abnormal activity on the part of the child that becomes deviant in terms of society's expectations of normality. Some children brought to psychiatric care because of excessive sexual activity give histories of early rape or other sexual exploitations on the part of adults. By virtue of the intense sexual stimulation offered to them, the children seek out all forms of sexual expression in order to carry out their compulsive needs to relieve their own tension. Consummated incest is most commonly observed between fathers and daughters, but, a *forme frustée* occurs frequently between mothers and sons.

Hypersexuality. A certain number of children are brought in because of abnormal sexual desires. A 9-year-old child was not only masturbating frequently but attempting intercourse with animals and children of both sexes and a variety of ages. He clearly demonstrated the compulsive aspect of the whole process and was quite free in talking about his own needs to relieve tension. He had been brought up in a Mexican culture where there was a good deal of overt sexuality, but his concerns had not arisen until a second marriage by his father to a puritanically obsessive mother, who was concerned about his sexual activity and acted in many ways as a stress to drive him into more and more overt sexual action.

Fetishism. In the process of separation of child from parent, it is frequently important—and normal—for the child to have an object related to the parent to which he can cling. This may be a blanket, a bottle, or a toy. Fetishism, however (and the use of objects to produce genital sexual satisfaction) comes much later, although it may, in many instances, be merely a translation from an earlier transitory object. The use of an inanimate object to enhance sexual satisfaction occurs normally in many adolescents. It is only when this becomes the primary choice of sexual satisfaction that the concept of sexual deviation is to be considered. It represents an immature solution of sexual identification and has to be handled as such.

Prostitution. Some girls become involved in excessive sexual activity early in their adolescence. In almost all instances this comes about as a result of exploitation of the child by adults. Such exploitation is nearly always accompanied by some form of adult stimulation of the child. In many instances this is akin to the overactive sexuality described above. The actual course of such deviant behavior is an increase in the

neurotic tension, which can only be relieved by excess sexual activity. Classically, these adolescents present a bland, hysterical personality pattern. The psychiatrist sees such deviant sexual behavior as a part of the total psychic activity of the individual. In this way, he is different from his legal colleague, who sees the symptom as a specific form of deviation from the practice of society and often as an insult against society. The medical problem is complicated, however, by the system that employs the girl and interferes with a clinical approach.

Prognosis and Treatment

Since the bulk of sexual deviations can be viewed as exaggerations of normal developmental processes, the physician must view them in the context of the over-all personality. Although the prognosis for change of many of these sexual deviations is guarded, it is enhanced whenever the physician has the opportunity to see the child early, to try to understand the total family pattern in which he lives, and to put the symptom in perspective as part of the child's total life experience. The child is often obsessive and compulsive about these symptoms. Treatment, therefore, should include any form of psychiatric treatment that attacks such neurotic manifestations in their relationship to the total life experience of an individual. Management becomes a combination of psychiatric and legal approaches. The law often separates such individuals from society but, unfortunately, equally often places sexual deviates of all sorts together. The stimulatory aspect of sexual deviations becomes exaggerated by congregating individuals with similar problems.

The best opportunity to treat these individuals is when treating the neurotic process. Unfortunately, the older the child becomes, the less the desire for treatment in such sexual deviations is present. Younger children may be more responsive because the entire family can be brought into treatment, and the abnormal relationships of the family situation may be brought out into the open and possibly dissipated.

There is no clear agreement on the part of psychiatrists as to how sexual deviates should be handled. To some extent this reflects not only the intrinsic pathology but also the impact of this pathology on society. Since therapists themselves are a part of the community, they often reflect the moral values of the community, and sexual deviations are particularly susceptible to being viewed with moral implications. The treatment, however, continues to be that of understanding the meaning of the symptom to the individual, understanding the compulsion and its repetitious activity, and attempting to break up the satisfying aspect of the process in order to relieve the individual's tension.

Suggested Cross References

41.7 SOCIOPATHIC PERSONALITY DISORDERS. III: ADDICTION AND ALCOHOLISM

ALFRED M. FREEDMAN, M.D.

ETHEL A. WILSON

Although precise statistics are unavailable, there is general agreement among medical, law enforcement, and other interested personnel that the number of children and adolescents using addictive substances has risen sharply in the 2 decades following the end of World War II.

Present day addiction among young people is characterized by the use of a variety of substances, sometimes sequentially, sometimes simultaneously. It is not opiate addiction per se that is most characteristic at this time but the addictive behavior with which many children and adolescents respond to the stresses, both objective and subjective, to which they are subjected. Remarkable ingenuity has been displayed by children and adolescents in discovering unlikely substances that produce intoxication or other desired psychic effects and often lead to addiction.

Addictive Substances

The simultaneous use of a wide variety of addictive substances has been observed among adolescents admitted to narcotic addiction treatment centers in metropolitan hospitals. Patients admitted for detoxification are commonly using heroin; amphetamines or barbiturates, or a combination of the two; and codeine-containing cough medicines at the same time. Detoxification under these circumstances must be accomplished with particular care, since withdrawal from barbiturates, particularly, may be hazardous unless done very gradually and under careful medical observation.

Opioids. The vast majority of American addicts in recent years have used heroin primarily, with morphine, meperidine, and other opioids following in that order. It has been observed that among many adolescent addicts the withdrawal symptoms occurring on discontinuance of heroin use are so mild that they have obviously been using greatly diluted heroin. Such addicts are said to be "addicted to the needle."

Marihuana. Although many young people who become narcotics addicts actually begin the use of heroin by the age of 16, a large proportion have used marihuana before becoming heroin addicts. The marihuana cigarettes commonly used today are prepared from the flowering tops of the hemp plant cannabis. It is known that marihuana differs from the opiates in that tolerance and physical dependence do not develop with its use and withdrawal symptoms do not appear on its discontinuance. The effects of the drug result from a relaxation of inhibitions, as is the case with alcohol.

Law enforcement officials have for many years considered the use of marihuana to be responsible for much criminal activity, but a number of studies of its use did not reveal a positive relation with violent crime. A group of marihuana users studied some years ago revealed that 13 per cent of the group began their use of the drug prior to adolescence, 64 per cent started between 12 and 17 years of age, and 13 per cent in their early twenties. The median age of "original addiction" was 15.3 years. The generally accepted knowledge of the use of marihuana by college and university students characterizes it as a significant adolescent activity at present, as it obviously has been for some time.

Amphetamines. Amphetamines have been used for therapeutic purposes, particularly in cases of narcolepsy, epilepsy, depression, behavior disturbances in brain-damaged children, obesity, and certain neurological disorders. Their addictive potential is now well recognized. The use of amphetamines by students and certain groups of workmen, particularly truck drivers, to induce wakefulness, is well known. However, their apparently widespread use, alone and in conjunction with other drugs, as part of the total addictive pattern, socially and psychiatrically, is more recent. Further, it is apparently world-wide, being prevalent in the Eastern as well as the Western hemisphere.

Barbiturates. The barbiturates, like the amphetamines, are known to be widely used by addicted adults, but there is now evidence of their substantial use by young heroin addicts. Many adolescents refer to their use of "goof balls," a term usually describing a combination of an amphetamine and a barbiturate.

Proprietary drugs. Proprietary drugs, particularly cough medicines containing codeine and substantial amounts of alcohol, are a relatively easy path to addiction. Among hospitalized adolescent addicts it has been found that tremendous quantities of such drugs have been taken either prior to or simultaneously with heroin.

Hallucinogenic drugs. Experimentation with hallucinogenic drugs, which alter sensory perception and produce hallucinations, has been conducted by adult intellectuals for some years. Quite recently, however, the use by university students of such substances as lysergic acid diethylamide (LSD-25), mescaline or peyote, and psilocybin has markedly increased. Such drugs have potential value in the exploration of altered states of consciousness if used under carefully controlled experimental conditions. There are, however, serious risks involved in their use, for they may precipitate psychosis, have serious side effects, or lead to addiction to other drugs.

Stramonium. Stramonium, a drug formerly used as a specific in treating asthma, has apparently been discovered by adolescents and used for intoxicative purposes.

Although the drugs enumerated above are most generally used by adolescents and young adults, a number of substances with intoxicating and addictive powers have been discovered by quite young children.

Glue. Glue sniffing has become sufficiently common within a few years to warrant legal action against the sale of glue to minors in several cities. The glue used in making model airplanes is both a stimulant and an intoxicant, and its use can have serious toxic effects. Superficial inquiry indicates that there are hundreds of glue sniffers, ranging in age from 8 to 14, in one small area of New York City. Records of arrests for glue sniffing indicate sharp increases in other American cities as well.

Gasoline. Gasoline addiction in children has been reported but may be much more common than is generally known. It has recently been recognized as a matter for concern by the welfare and legal authorities in some of the developing nations of Africa. It is logical that so common and easily available an intoxicant should be used where there is not likely to be money for the purchase of drugs or similar substances: automobiles can be found anywhere.

Alcohol. Alcoholism is generally considered an adult disorder that develops over a period of many years. However, a number of studies indicate that the use of alcohol by adolescents and young people is very common. Whether it is accurate to refer to children or

adolescents as alcohol addicts is questionable, particularly since the classification of even adult users of alcohol is very complex. However, an increasing number of young people are arrested and convicted of drunkenness or related charges in many parts of the world today, and some young people have clearly reached a state of dependency on alcohol.

Tobacco. Cigarette smoking, the near universal addiction of the mid-20th century, has been described as common along 9-, 10-, and 11-year-old children, and adolescents of 18 or 19 are already heavy smokers.

Epidemiology

A limited number of studies have been made of the incidence and prevalence of addiction and the distribution of narcotics addicts in the United States. Since most data are available from the records of law enforcement agencies and hospitals to which addicts have been admitted, the data, incomplete as they may be, provide information largely on adolescents and adults. A broad study of narcotics use among adolescent boys was done by a group at New York University between 1952 and 1956 (Chein et al.). Available for study were the records of all boys between the ages of 16 and 21 who had in the period 1949 to 1952 come to the attention of some official city agency in connection with narcotics. The list comprised 1,844 boys who had been involved in the use, possession, or sale of drugs.

Groups of boys interviewed during this research provided specific information on the steps that had led to addiction or, in the case of nonusers, had resulted in their rejection of drug use. Most of the users had heard about heroin before they actually had an opportunity to try it, usually at about 15 years of age. By that time, most of them had already seen someone inject or "snort" heroin. For most boys the first opportunity to use the drug came at about the age of 16 or 17, but a sizable group were 14 or less when this occurred. Sixteen seemed to be the age at which the boys were most likely to become users, with a greater proportion going on to regular use from this age group than from those who were either younger or older than 16 at first try.

Of the boys who served as a control group for the study—those who did not become users—40 per cent had also been given the opportunity to try heroin between the ages of 15 and 17, but none of them did so. The importance of learning what factors differentiated these boys from the previous group cannot be overemphasized. Authors of the study suggested that among the factors that did influence the nonusers were age; pertinent information about the result of drug use, which had a deterrent effect; and the boys' interpretation of the attitude of significant adults to drug use.

The urban neighborhoods in which drug use flourished, according to the above study, were the most underprivileged, crowded, and dilapidated areas of

the city. They were further characterized by the lowest levels of income and education and the greatest breakdown of normal family structure.

Another study of drug use among juveniles and young adults conducted in Chicago at about the same time as the New York study revealed a similar situation. The areas in which the highest concentration of heroin addicts was found were also characterized by the highest rates of other social problems—low family income, low social status, deteriorated housing, a high proportion of recent migrants to the city, absence of effective community organization, high rates of adult crime, and lack of family and community control over the conduct of young persons. Because this group of heroin users seemed to have indulged in delinquent behavior before becoming addicted and did not commit crimes of a more serious nature after addiction, it was concluded that their delinquency was not a result of heroin addiction but a reflection of the same interests and problems that had led to drug use.

The data provided by the above studies is to a great extent equally valid today, but there is sufficient evidence to conclude that changes have occurred in the past decade, not only in the number or proportion of juveniles using drugs but also in the socioeconomic strata from which such users are drawn. There appears to be a steady increase in the number of arrests of young university students for possession, use, or sale of drugs of all varieties. Newspaper reports exposing such activities in wealthy suburbs of American cities are now quite frequent. Such information only emphasizes the complex etiology of drug addiction and clearly destroys the validity of assigning complete responsibility to low socioeconomic class, lack of educational opportunity, abnormal family life, or a particular kind of "addict personality." Although all these factors and, in all probability, physiological ones as well enter into the development of addiction, it must be recognized that addictive behavior has multifactorial origins, and disciplined scientific investigation is required for their elucidation.

Treatment

The difficulties in successful treatment of drug addicts have been demonstrated many times and over a prolonged period of time. Most pertinent in a discussion of young addicts is the study done by the Columbia University School of Public Health in 1957 (Alksne et al.). This was a follow-up of discharges from Riverside Hospital, established in New York in 1952 for the treatment of addicts under 21 years of age. Of 147 discharges interviewed, only 19 per cent were seen outside a prison or a hospital. Only 5 per cent of the 147 had abstained from the use of drugs after leaving the hospital. The 147 ex-patients were all who could be located of a total of 247 who had been admitted to the hospital in 1955. It was as-

certained that 11 of the 247 were dead, an unusually high death rate for this age group. It seems that the majority of these deaths were due to overdoses of narcotics. It is also known that among addicts of all ages there is a high incidence of infectious diseases attributable to the use of shared unsterile needles for injecting heroin—such diseases as malaria, tetanus, syphilis, bacterial and mycotic endocarditis, and infective hepatitis.

Because of the demonstrated failure of most treatment programs for addicts, it becomes necessary to recognize that the emphasis on institutional programs, all of which have had as their goal complete abstinence from narcotics, may be misplaced. In the case of children and adolescents, certainly, it is difficult to accept maintenance on drugs of any type as a satisfactory aim, although that is now being seen as an experimental possibility for some adults. The aim of a treatment program designed for children should be not only withdrawal from the use of drugs but social and medical rehabilitation that leads to integration into the established institutions of society—school and employment.

Since the child's voluntary indulgence in glue sniffing, gasoline inhalation, or marihuana smoking is apparently an attempt to withdraw from the real world in which he finds himself, one must accept the fact that basic changes in that world would contribute to a greater willingness by the child to experience and grow in it. However, basic social change occurs slowly, and the glue sniffer cannot be put into a Deepfreeze while that is occurring.

There must be a careful examination of the society in which addiction develops and spreads. Attempts must be made to provide for children those social institutions, particularly schools and recreation, that engage them in experiences from which they do not seek to escape. At the same time, those children who, for whatever reason, have succumbed to drug use must be provided medical and psychiatric care that is realistically oriented to this disorder. The changes in patterns of drug use, the increasing involvement of young people from all socioeconomic classes, and the movement of drug dependence downward into ever younger groups of children suggest the widening dimensions of the problem.

Chapter 42

Psychiatric Disorders of Childhood.

III: Psychotic and Brain Disorders

42.1 PSYCHOTIC DISORDERS. I: CLINICAL FEATURES

LEON EISENBERG, M.D.

History

A brief historical note may serve to emphasize the recency of the renaissance of interest in childhood psychosis. Though the term "dementia praecox" was coined in 1860 by Morel to describe a psychosis in a 14-year-old boy, relatively little attention was given to the form of the earliest manifestations of dementia praecox by subsequent students of the disorder. Kraepelin is often cited as stating that onset occurred before the age of 10 in 3.5 per cent of 1,054 patients he reported. These were, however, retrospective diagnoses, and the differentiation between premorbid personality trends and the onset of psychosis per se was a matter of "uncertain and arbitrary" judgment from the history supplied to the physician. Bleuler, with a more specific concept of schizophrenic psychopathology, stated in 1911: "With a relatively accurate case history, one can trace back the illness to childhood, even to the first years of life, in at least 5% of cases." The limitations of his experience with children are apparent in the further comment: "At the present time we know of no differences between the infantile and other forms of the disease. . . . The prognosis of those cases in which the onset of the illness occurred before puberty does not appear to be too poor for the next few years . . . ; however, the case histories of adults admitted to the hospital show that at least part of these early cases relapse and then usually become markedly deteriorated."

The first specific consideration of childhood schizophrenia as a separate category dates from the earliest papers (1905-1908) of deSanctis, who proposed the term "dementia praecocissima" to designate this clinical subdivision. However, deSanctis included not only

cases of childhood schizophrenia as the term is employed today but also others who had chronic brain syndromes and severe mental deficiency. Such wastebasket diagnoses, the loose usage of "childhood" to include onset as late as 16 or 17 years of age, and the preoccupation of psychiatrists with hospitalized adults—all contributed to a growing disbelief in the reality of schizophrenia in childhood. As recently as 1942, Bender wrote: "There are those who do not believe in childhood schizophrenia, not having seen a case. At the best, none of us have seen very many cases in which we could make a definite diagnosis, not knowing the acceptable criteria." Yet, not more than 10 years later, Despert could write: "Although there are still people who believe that there is no such thing as schizophrenia in childhood, generally speaking we might say that the concept of childhood schizophrenia has passed from non-recognition to over-recognition."

Despert's warning against "over-recognition" or misdiagnosis has even greater cogency today, when terms like "autism" and "childhood schizophrenia" have entered the common parlance. The defective or brain-injured child who fails to be labeled psychotic at some way station in his parents' odyssey through out-patient and in-patient services is rare indeed. Thus, it seems appropriate to place emphasis on specificity in diagnosis—not as an obsessional exercise in pigeonholing but as a necessary precursor for systematic investigation of cause, course, and treatment.

Classification

The American Psychiatric Association's standard diagnostic manual states that psychotic disorders are characterized by personality disintegration, faulty evaluation of external reality, impaired ability to relate to others, and ineffective work performance. Prominent manifestations include severe mood disturbance, incongruity between mood and thought, faulty stream of thought, delusions, hallucinations, and bizarre behavior. These descriptive terms devolve from the clinical study of adults; they serve as a general framework for the diagnosis in childhood but must be evaluated against age-

appropriate behavioral norms for children. Failure to take developmental age into account can lead to false positives, based on spurious analogies between child and adult behavior, and to failure to recognize psychosis if the clinical picture in a child does not replicate the full syndrome seen in the adult.

Some child psychiatrists espouse the view that diagnostic differentiation within the group of severely disturbed children is neither useful nor possible. It is indeed true that there are cases in which no firm diagnosis can be made, but the great majority can be assigned to categories that have therapeutic as well as prognostic implications. The literature on childhood psychosis is replete with discrepancies in the research and clinical findings reported by different investigators; in large part, these differences stem from differences in diagnostic practices, which result in non-comparability of the populations under study.

To stress the diversity of the disorders which may present a clinical picture of psychosis, a tentative classification of psychotic disorders in childhood is set forth below.

- I. Psychoses associated with impairment of brain tissue function
 - A. Associated with intoxication (atropine, bromides, stramonium, cortisone, etc.)
 - B. Associated with metabolic disorders (pellagra, amaurotic idiocy, etc.)
 - C. Associated with degenerative disorders (Schilder's disease, dementia infantilis, etc.)
 - D. Associated with infections (juvenile paresis, encephalitis, etc.)
 - E. Associated with convulsive disorders (temporal lobe epilepsy, dysautonomia, etc.)
 - F. Associated with trauma
 - G. Associated with neoplasm
- II. Psychoses without known brain tissue impairment
 - A. Autistic psychoses
 1. Early infantile autism (Kanner)
 2. Symbiotic psychosis (Mahler)
 - B. The schizophrenias
 1. Simple
 2. Acute undifferentiated
 3. Paranoid
 - C. Psychoses associated with maturation failure
 1. Atypical child (Rank)
 2. Childhood psychosis (Szurek)
 3. Childhood schizophrenia (Bender)
 4. *Pfropfhebeaphrenia* (Weygandt and Kraepelin)
 - D. *Folie à deux*
 - E. Manic-depressive psychosis

Subclassifying the functional psychoses poses a difficult problem. No two authorities agree fully on the use of terms; some of the nonspecific diagnostic labels ("atypical child," "childhood psychosis") include conditions such as dementia infantilis, which this classification assigns elsewhere. The intent of this schema is to emphasize clinical specificity and to guide the student to an awareness of the differences in concept represented by the differences in labels. Subhead-

ings A, B, D, and E in part II represent clinically definable and mutually exclusive categories. Subheading C is a residual category to cover terminology in disagreement with the principles of this classification but nonetheless meriting inclusion because of the frequency of their use.

Psychoses Associated with Impairment of Brain Tissue Function

These disorders may mimic the clinical picture of the functional psychoses in all respects. They are usually differentiable by history, clinical features, and associated neurological and laboratory findings. Central nervous system pathology should be suspected in the presence of fulminating onset, marked disorientation, intellectual deterioration, memory impairment, and lability of affect. Only if the clinician is prepared to consider the presence of a central nervous system disease will he undertake specific diagnostic investigations. The identification of disorders subject to specific corrective measures can be life-saving for the patient. But even when the condition is one with a progressive and irreversible course, correct diagnosis is important in assisting the family and in sparing them futile and costly therapeutic endeavors. These disorders are covered in detail in Section 42.3 by Laufer.

Psychoses without Known Brain Tissue Impairment

These disorders differ clinically as well as neuropathologically from the syndromes associated with brain tissue impairment. *Consistent* structural or chemical abnormalities regularly associated with these clinical conditions have yet to be demonstrated; whether or not they can be ascribed to a psychogenic etiology remains to be determined.

Autistic psychoses

Early infantile autism. This was described by Kanner in 1943. The pathognomonic disorder was seen as "the children's inability to relate themselves in the ordinary way to people and situations from the beginning of life." The children did not withdraw from formerly existing participation with others, as is the case in schizophrenia, but rather from the start displayed an extreme autistic aloneness. Parents report that these children as infants failed to assume an anticipatory posture before being picked up and never displayed the molding that the normal child shows when cradled in his parents' arms. Parents, initially pleased by the child's "goodness"—that is, his ability to occupy himself for long periods without requiring attention—later become distressed by the persistence of this isolation when they observe that their arrival and departure are matters of indifference to the child.

The second distinctive feature noted by Kanner was failure to use language for the purpose of communication. In 3 of his original 11 cases, speech failed to de-

velop altogether. The remaining children rapidly developed a precocity of articulation that, coupled with unusual facility in rote memory, resulted in the ability to repeat endless numbers of rhymes, catechisms, lists of names, or other semantically useless exercises. The parroting of words intellectually incomprehensible to the child brings into sharp relief the gross failure to use speech to convey meaning. The repetition of stored phrases and the presence of failure to recombine words into original and personal sentences give rise to delayed echolalia, pronominal reversal, literalness, and affirmation by repetition rather than by the use of yes.

A third characteristic is an anxiously obsessive desire for the maintenance of sameness, which results in marked limitation in the variety of spontaneous activity. These youngsters regularly display fear of new patterns and, once having adopted a pattern, incorporate it into the restricted set of rituals, which are endlessly iterated. Thus, a walk always has to follow the same course; bedtime to consist of a particular set of rituals; and repetitive activities like spinning, turning lights off and on, and flushing toilets occupy the child for long periods. Attempts to interfere with the pattern produce rage.

Fourthly, the children display a fascination for objects, as distinct from their poor or absent relation to persons. So intense is this relationship that minor alterations in the arrangement of objects, not ordinarily perceived by the average observer, are at once apparent to autistic children, who exhibit panic until the change has been undone.

These children are separable from mentally retarded or brain-injured children by their good intellectual potential. In the children who speak, this can be discerned by the extraordinary, if perverted, use of language and the feats of unusual memory. In mute children, though the evidence is less persuasive, there is facility with performance tests, frequently at or above age level. Thus, Kanner has delineated a syndrome that is differentiated from childhood schizophrenia by virtue of detachment starting no later than the 1st year of life and from oligophrenia by evidence of good intellectual potential.

Infantile autism has become increasingly fashionable as a diagnosis but with concomitant dilution of its specificity. The mere presence of autistic phenomena (observable in many defective and brain-injured children) is regarded by some as establishing the diagnosis of infantile autism, even when associated findings point clearly to other primary disorders. In evaluating reports of etiological or therapeutic studies on autism, it is essential to note the criteria by which the diagnosis has been established.

In a review of 100 cases of infantile autism seen on Dr. Kanner's service,¹ few neurological or electroencephalographic (EEG) abnormalities and infrequent reports of complications of pregnancy or parturition were noted. Of the 200 parents, only 6 presented gross

psychiatric abnormalities; of the 400 grandparents and 373 listed uncles and aunts, only 12 had come to psychiatric attention for major mental illness. Similarly, of the 131 known siblings, only 3 were autistic, and only 7 others displayed psychiatric disturbances.

The personality patterns of the parents revealed an unusually high percentage of obsessive, intelligent, and cold individuals; 87 per cent of the fathers and 70 per cent of the mothers had been to college, proportions greatly in excess of those characterizing a random sample of other private patients. A large number of the fathers were professional people who had attained distinction in their fields of endeavor. Although it is tempting to speculate that the emotional detachment, obsessiveness, and coldness of the parents may in some way be related to the syndrome in the children, it is noteworthy that at least 10 per cent of the parents did not fit the stereotype, and even those who do fit it have borne and reared other normal children. Moreover, similarly rigid parents have been seen who had not produced autistic offspring. If there is a relationship between child and parent characteristics, its significance is not immediately evident. Both may be manifesting the action of genetic factors, fully apparent in the child but only partially expressed in the parent; parental behavior may have induced the behavior in the child; or the experience of living with a severely disturbed child may have led his parents to withdraw from involvement with him.

Although the Hopkins studies have been negative with respect to organic abnormality, other investigators have drawn different conclusions. Knobloch and Grant stated that neurological disorders underlie the majority of cases of autism and schizophrenia in childhood. Schain and Yannet have described 50 cases of autism from the Southbury Training School; they reported a high incidence of seizures, EEG abnormalities, and associated neurological findings, but there is considerable question as to the appropriateness of the diagnostic allocation. White et al. have reported a high percentage of EEG abnormalities (53 per cent) under promazine sedation in childhood schizophrenics, an equally high percentage in nonpsychotic behavior disorders, but only 10 per cent among neurotic and none among control cases. These studies, together with a number of reports on small groups of autistic children with gross EEG or neuropathological disorders, are open to serious question as to diagnostic specificity.

Ferster has developed an interesting and provocative hypothesis on the genesis of autistic behavior by using an operant conditioning model. He provided a logical framework for therapeutic programs based on enlarging the autistic child's limited behavioral repertoire by positive reinforcement methods. Ferster's model has the striking virtue of being subject to experimental analysis. Research currently under way by Ferster and his associates is designed to evaluate the clinical efficacy of a therapeutic program based on his hypothesis.

A follow-up study of 63 autistic children demonstrated that the presence or absence of useful language by the age of 5 differentiated sharply between two groups of autistic children. Of the 30 children without effective speech, only 1 child subsequently attained a marginal social adjustment, and this child has since required psychiatric hospitalization. In contrast, about half of the 31 children with language have been able to maintain a social adjustment in the community and have progressed in school at about age level. Even the successful youngsters, however, continue to be characterized by an impoverishment of human relationships, a lack of social competence, and a schizoid personality. Many are painfully aware of their own maladroitness in interpersonal relations and tend to seek out solitary occupations. Outcome seemed to be more a function of the severity of the disorder than of the type or amount of treatment. However, it should be emphasized that efforts at psychiatric care—including residential placement, psychotherapy, and psychotropic drugs—are strongly indicated pending the demonstration of specifically effective treatment modalities.

Symbiotic psychosis. Mahler has proposed that psychoses of early childhood should be divided into autistic and symbiotic varieties. The symbiotic disorders are characterized by later onset and by symptoms of anxiety, which may mount to panic when attempts are made to separate the child from his mother; that is, the psychopathology in such cases reflects failure at self-differentiation after the initial developmental stage of relating to the mother had been attained. If symbiotic psychosis is indeed a real clinical entity, it must be far less common than infantile autism, itself uncommon, in view of the infrequency of clinical reports.

The schizophrenias. Among psychotic children there are a considerable number whose clinical manifestations meet the criteria set forth for the diagnosis of schizophrenia as it is seen in the adult. The term "schizophrenia" should be restricted to this group in view of the uncertainty about the relationship of the other psychotic syndromes in children to the adult schizophrenias. The term has been used in the plural, the schizophrenias, to emphasize the heterogeneity of the syndromes classified under this rubric. These schizophrenic reactions in childhood probably do not occur before the age of 8 years and are seen with increasing frequency as children approach adolescence.

The proposed subdivision into three types—simple, acute undifferentiated, and paranoid—reflects clinical experience in which the other types described in adults are either nonexistent or so rare as not to warrant listing here.

Psychoses associated with maturation failure. This residual category is intended to accommodate a heterogeneous set of clinical syndromes embodied in terminologies at variance with this classification but so widely used as to require identification. With greater specificity of diagnostic practice, many cases currently

labeled under this heading would be reallocated to the organic psychoses, to autism, or to schizophrenia.

The heterogeneity of the cases associated with maturation failure make impossible a meaningful comparison of etiological and therapeutic findings. Thus, whereas Bender reported a 40 per cent rate of schizophrenia among parents, Creak and Ini noted a low incidence of psychiatric abnormality in the parents of the psychotic children they have examined, a finding comparable to our observation among parents of autistic children. The one systematic search for chromosomal abnormalities in schizophrenic children thus far reported was completely negative.

Attempts to evaluate therapeutic results are confounded both by diagnostic uncertainties and by differences in criteria for outcome. Whereas Bender is persuaded of the value of electroshock, Clardy and Rumpf reported the contrary based on observations of children earlier seen at Bellevue. Szurek reported, after intensive psychotherapy, a 14 per cent improvement rate among cases of childhood psychosis, whereas Brown found a 37 per cent improvement rate after intensive psychotherapy and therapeutic nursery care for atypical children. The over-all figures from Hopkins and from Bellevue indicate that about one quarter of the children were able to attain an adequate social adjustment in the community.

Atypical child and childhood psychosis. Rank and Szurek have indicated in their definitions for these terms that they do not consider it fruitful to differentiate among schizophrenia, chronic brain syndromes, mental defect, and severe neurosis in assigning cases to these categories, which appear to be coterminous; any child who displays severe developmental deviations with marked impairment of social adjustment appears to qualify for inclusion.

Childhood schizophrenia. According to Bender, childhood schizophrenia is "a clinical entity occurring in childhood before the age of 11 years which reveals pathology at every level and in every area of integration and patterning within the central nervous system, be it vegetative, motor, perceptual, intellectual, emotional, or social." The fundamental pathological process is taken to be a diffuse encephalopathy, an inference from clinical considerations, since there are no neuropathological reports. Bender suggested subclassification into three clinical types: the pseudodeficient or autistic regressive type; the pseudoneurotic or phobic, obsessive-compulsive, hypochondriac type; and the pseudopsychopathic or paranoid, acting out, aggressive antisocial type. Follow-up studies from Bellevue are reported to reveal that some two thirds of the cases were diagnosed in later adolescence or adulthood as schizophrenic. There is, of course, the question about the independence of the second diagnosis insofar as knowledge of the earlier diagnosis may have influenced the clinician who saw the patient as an adult. However, it seems from these follow-up studies that a significant proportion of the cases classi-

fied as childhood schizophrenia by Bender display adult schizophrenic syndromes.

Pfropfhebephrenia. Kraepelin coined the term "hebephrenia engrafted upon defect" to characterize the psychotic states observed in a colony of mental defectives. Such disorders may represent: (1) psychosis and mental defect, both secondary to central nervous system disease; (2) deteriorated, functionally defective end states of originally psychotic children; and (3) psychotic episodes in primarily defective children. Bizarre mannerisms are frequent among the inmates of the traditional colonies for defectives; some represent the behavioral consequences of the neglect and deprivation so frequently accorded these unfortunate children; others may be part of the basic central nervous system disease. But even these latter symptoms may be correctable by appropriate environmental manipulations, since every living organism can learn. Modification of the aberrant behavior may free the child for the adoption of more constructive traits, or it may serve the purpose of making him more acceptable in the social group by removing characteristics that stigmatize him.

Folie à deux. *Folie à deux* is an induced or imposed psychosis in which a relatively healthy person shares the symptomatology of a psychotic person with whom he has a close relationship. The disorder appears in the context of an intense relationship between two persons, the great majority of which are family relationships. By definition, the relatively healthy partner is able to abandon the symptoms when separated from the psychotic partner.

Manic-depressive psychosis. True instances of this disorder in childhood are exceedingly rare. Anthony and Scott, in a scholarly review of the literature, were unable to uncover any instances in children younger than 11 who met the following criteria: a psychiatric state conforming to the classical clinical description, a positive family history, cyclothymic premorbid personality, periodicity, evidence of an endogenous illness in that cycles alternate with minimal reference to external events, psychotic severity, and current rather than retrospective assessment. Much of the controversy in the literature about the existence of depressive illness in childhood stems from a confusion of a psychodynamic interpretation of the meaning of symptoms with a clinical diagnosis based on overt behavior and longitudinal course. By the latter criteria, manic-depressive psychosis appears never to occur in early childhood and to be exceedingly rare prior to adolescence.

Prognosis

The foregoing review will have made it evident that no over-all statement about outcome is justified. For those disorders ascribable to defects in central nervous system function, the prognosis is that of the underlying organic disorder. For the functional psychoses, prognostic statements are just as difficult to offer,

TABLE I
Outcome of Childhood Schizophrenia

Author and Year	Number Recovered	Case Total
Before 1940		
Sukhareva (1932)	0	25
Grebelskaya-Albatz (1934)	1	22
Lurie et al. (1936)	1	13
Lutz (1937)	0	20
Potter and Klein (1937)	1	14
Creak (1937)	3	9
Despert (1938)	3	29
Total	9 (7%)	132
Since 1940		
Lurie et al. (1943)	4	17
Bender (1951)		
Shock-treated	36	143
Refused shock treatment	2	50
Eisenberg (1956) (autism)	17	63
Szurek (1956) (psychosis)	14	100
Brown (1963) (atypical child)	47	129
Total	120 (24%)	502

since it seems certain that in this category are entities of a wide variety of types. The field may in many respects be comparable to the state of mental deficiency 50 years ago, before the success of efforts to separate out the many different syndromes that share only the final common manifestation of defective intelligence.

Rutter has drawn attention to the I.Q. score of the psychotic child as an important prognostic indicator. Despite the clinical impression of the unreliability of I.Q. testing in such children, he found a correlation of 0.80 between initial scores and those on follow-up. Moreover, the likelihood of clinical recovery seemed more related to I.Q. than to speech function, with recovery rare in children testing at less than 50. He suggests, and I believe correctly, that my earlier observations on the presence or absence of useful speech by age 5 as a predictor of outcome may have been "largely due to the high correlation between absence of speech and low intelligence."

A tabular comparison of the outcome of cases of childhood psychosis reported in literature before and after the year 1940 indicates the change in the concept with time. The much better results reported in the recent era suggest, in the absence of any evidence of specific treatment methods, that contemporary clinicians include cases previously given other diagnoses (see Table I).

Current Status

The so-called functional disorders remain the subject of considerable dispute among competent and experienced clinicians. Resolution of the conflicting views

awaits careful investigation based on new methods of study as well as greater conceptual clarity.

The argument for careful clinical specification of subtypes rests on therapeutic, etiological, and prognostic grounds. To evaluate the comparative effectiveness of current or future treatment methods, one must begin by delineating comparable populations and assigning them to control and experimental groups. The uses and the limitations of penicillin, for example, could hardly have been ascertained if clinicians had not been able to differentiate colds, pneumonias, and neoplasms. This thesis holds with even greater forcefulness for attempts to isolate etiology. Abnormal metabolic findings that may characterize one clinical syndrome may be lacking in a second; if both are indiscriminately presented to the biochemist, his findings will be puzzling and inconsistent. Finally, if the clinician is to be able to offer meaningful prognoses to assist parents in planning for the care of their children, he must be able to differentiate disorders that have different likelihoods of favorable outcome. Differential diagnosis is no academic exercise; it is the very stuff of medicine.

Suggested Cross References

Schizophrenia and other psychotic disorders are also discussed in detail in Chapters 15, 16, and 17 in Area F, on the psychiatric syndromes of adults. Organic brain disorders of children and mental retardation are discussed in detail in Section 42.3 and in Chapter 22, respectively. Therapy of childhood psychosis is the subject of the following section, Section 42.2.

42.2 PSYCHOTIC DISORDERS. II: TREATMENT

RUTH L. LA VIETES, M.D.

The therapy of childhood psychosis is complicated by three factors. One is the variety of behavioral syndromes subsumed under this diagnosis. If this is indeed one disease, it encompasses behaviors that range from virtual unawareness of the human environment to a disposition toward disorganized thinking under environmental stress. A second factor is the considerable difference of opinion as to the etiology, since therapeutic choice depends on the causal theory held by the therapist. The third factor is the poor prognosis, especially with the severely psychotic child; this causes therapists to engage in therapeutic experimentation, with each new approach appearing to have initial success. Although various therapeutic interventions are discussed separately here, they are usually combined. It would not be unusual for a schizophrenic child to receive elements of all of the therapeutic modalities discussed below, although usually one or another receives greater emphasis.

In the discussion which follows, the designation "childhood psychosis" is used to mean psychosis without known brain tissue impairment. This includes the form appearing in early infancy (early infantile autism), later infancy (symbiotic psychosis), later childhood (childhood schizophrenia), and adolescence (schizophrenia).

Psychotherapy

The first efforts at the psychotherapy of childhood schizophrenia were made in the late 1940's. Initially, psychotherapeutic techniques were derived from the

treatment of neurotic children. When these proved fruitless, particularly in the more severely disturbed children, therapists experimented with innovative methods, which were initially based on trial and error and subsequently brought into existing theoretical frameworks. Since psychotic children tended to collect in special centers set up for their study and care, therapeutic techniques of varying types became established in these separate centers, which have, by and large, continued to refine their methods. As a result of this and the generally poor prognosis, there is no systematized psychotherapy of childhood schizophrenia, and varying methods are found from one center to another.

The type of therapeutic intervention employed in childhood psychosis depends on the therapist's etiological theory of the disease. For those who espouse vigorous psychotherapy, etiological emphasis lies in deficient life experience of the child, due either to constitutional inability to elicit or benefit from normal experience or from a pathological environment. Among the theories underlying psychotherapy are the following: (1) The child retreats as a result of gross emotional deprivation or painful contact with people. (2) The child is unable to erect an inner maternal image and thus cannot develop ego or superego, cannot use identification or introjection, and cannot establish a sense of reality. He therefore withdraws to an omnipotent world, which constitutes an attempt at restitution of the lost or never achieved maternal object. (3) Autism is a psychotic defense in which the ego restores oneness with the object as a delusional defense against separation from the mother. (4) The absence of crucial experience at some critical period causes an inability to endow human beings with appropriate significance.

There is considerable conflict of opinion as to the ultimate effectiveness of psychotherapy for psychotic children, although there is little doubt that it frequently results in symptomatic improvement. Autistic children may achieve socialization, enabling them to function outside of a special institution, while retaining considerable personality limitation and ego vulnerability. The resolution of intrapsychic conflict produces relief of anxiety or reduction of psychotic defenses, but in childhood psychosis, unlike neurosis, the intrapsychic conflict does not appear to be the cause per se of the disease; therefore, one could not expect to achieve resolution of the illness. It is possible that no matter how early the illness is detected, certain crucial experiences have been missed that make the course irreversible. Prognosis depends on the degree of severity of the illness, ability to alter contributing factors in the parents, the age at which treatment is instituted, the quality of treatment, and the vigorousness with which it is pursued. The personality characteristics necessary to do psychotherapy with psychotic children are optimism, persistence in the face of little reward, firmness and strength, and the ability to withstand countertransference tempta-

tions, particularly that of overidentification with the child.

Generally, psychotherapeutic techniques with psychotic children fall into three phases, based on the functional level of the child, regardless of etiology or previous treatment.

Markedly disturbed autistic children may be able to undergo only the first or possibly the second phase. Less disturbed or borderline children may begin with the third phase.

First phase: Overcoming the autistic barrier.

Methods for penetrating the shell of the withdrawn, regressed child have been extensively studied. In order to develop the initial awareness of human beings, the therapist establishes himself as an all important factor in the child's life, often caring for him physically, offering unconditional acceptance, using the child's receptive channels by mirroring them, removing obstacles to gratification, and helping him express his impulses while gratifying them safely. Music, rhythmic activities, food, extensive physical contact, and understanding and participation in the child's primitive magical language, gestures, and fantasies may be used by the therapist to insinuate himself into the behavior pattern of the child. The child may be encouraged to relive primitive stages of development that have been previously missed or have been unsatisfactory—for example, sucking on a bottle or messing with clay as a substitute for feces. Certain necessary frustrations, such as the control of destructive behavior, come from the same therapist who gratifies so freely, thus providing the basis for object relationship.

Second phase: Development of ego functions.

With the therapist acting as an auxiliary ego and providing such necessary ego functions as translating primitive impulses into language, acting as a stimulus barrier, interpreting events, etc., therapy concentrates on the development of the ego functions of relationship to persons, perception of reality (awareness of self and external reality), postponement of gratification, and clarification of impulses and feelings. The therapist acts as a boundary while helping the child establish his own boundaries. Thus, the child is helped to cope more successfully with internal and external pressures, developing more appropriate behavior.

Third phase: Resolution of intrapsychic and interpersonal problems. This phase, the goal of which is the understanding of the conflict that caused the withdrawal, is applicable to those psychotic children who can utilize it. It is somewhat similar to the treatment of severe neurosis but with considerable modification of technique, such as the therapist's active participation in and limitation of fantasies so that they do not become too frightening, the emphasis on intellectual controls, regulation of life outside of therapy, working with the part of the ego that is intact, and utilization of the corrective relationship to the therapist to provide understanding of previous frustrating

experiences. The resolution of internalized conflicts and relief of anxiety attached to primitive fantasies result in a freeing of additional sources of ego strength and in the development of more adaptive gratifications than the previous pathological interaction.

Group Therapy

In the past few years, group psychotherapy with psychotic children has been used in a few centers. Small groups of children with regressive behavior and disturbances in self-identity, perception of reality, and use of communicative language meet several times weekly with one or more therapists. Isolation, panic, and further regression may occur initially, but in time group formation occurs, as the children become aware of each other and the therapist. This permits the introduction of group activities and structure, which are tolerated for longer and longer periods of time. Finally, interpretations are given regarding the difference between reality and nonreality, self and object, and the relationship between feeling and behavior. Children perceive their own and others' behavior as dystonic, which helps to develop control. Therapy of the children is usually combined with group or individual therapy of the parents and, where possible, with school attendance.

It is felt that the therapeutic group develops a group ego, which provides support for the defective egos of the individual patients. For symbiotic psychotic children, the therapeutic symbiosis they require is provided by the group ego. Results include the achievement of communicative speech, some measure of self-identity, and movement upward in the development scale, such as achievement of toilet training. The avoidance and self-protective aspects of their behavior, such as ritual and mannerisms, may decrease.

Milieu Therapy

With the rise of residential and day treatment programs for children, the importance of milieu in the treatment of psychotic children received increasing attention. The protean nature of the impairments in this illness sometimes calls for intervention in all life experiences. Programs that provide care for a major period of the child's life are able to provide a controlled, consistent milieu that is in itself therapeutic.

Such programs consciously attempt not only to integrate all the child's experiences—physical care, education, recreation, psychotherapy, etc.—but also to develop an attitude on the part of all personnel, professional and nonprofessional, that meets the child's dynamic needs. Various centers define these needs differently. The emphasis may be on giving the child permission to regress to previous stages of psychic development and to relive them with therapeutic personnel; on providing the child with sensitively timed doses of human contact, according to his tolerance; or on providing a clear cut structure of expectation to which the child is expected to adapt. The therapeutic

prescription carried out by the staff strives to be internally consistent, in accordance with the theoretical understanding of childhood schizophrenia held by the center.

Milieu therapy provides multiple activities; a peer group that allows identification, necessary regression, or acting out; flexibility in individually designed programs; multiple adults from whom the child can choose; clinically controlled and manipulated experiences; an atmosphere of being accepted and wanted rather than of being deviant; and opportunities for diluted relationships. One of the important requirements in establishing a totally therapeutic atmosphere is to provide the entire staff with organized controlled opportunities to work out their own feelings of rivalry with each other; of resentment, guilt, and helplessness with the children; and of any other factors that interfere with optimum consistency of efforts.

Consciously designed milieu therapy necessarily takes place in selected residential or day treatment centers where a major segment of the child's time is spent and where sufficient time and personnel are available for this time-consuming effort. Psychotic children are referred for such programs on the basis of the degree of psychopathology in the child and parents and the ability of the home and community to tolerate their behavior and provide necessary services. Some psychopathological features for which milieu therapy is particularly recommended are inability to maintain contact with parents, lack of experience of gratification in interpersonal relationships, and the combination of uncontrollable impulses with very weak ego structures.

Results of intensive programs are generally good, considering that the most severely disturbed psychotic children are selected for them. Since these programs combine the best of all available therapies while adding the special dimension of milieu therapy, they should and do produce the best results, although they are the most costly.

Educational Therapy

Although educational principles are commonly used in combination with other treatment modes and enter into all psychotherapy of psychotic children, in some centers the educational experience is the definitive intervention with the child. This form of treatment has been receiving greater emphasis with psychotic children in the last decade as other therapeutic methods have yielded disappointing results.

Educational therapy is generally in the hands of teachers, usually with psychiatric supervision or consultation. Emphasis is placed on the external reality demands, structure of the classroom situation, and ego modes of functioning. Anxiety is reduced by clarity of expectation and predictability. Children are taught perceptual discrimination, relationships in time and space, functioning of the body, and the realities of various social relationships. They are trained to put

thoughts and feelings into words, to coordinate motor activity, and to master the operational tools for learning. The capacities to play, to learn, and to participate actively are encouraged. The strengthening of skills through emphasis on intellectual functioning serves to promote self-esteem and identification with peers. The teacher addresses himself to the healthier aspects of the child's functioning by imposing a graded series of reachable challenges. The defenses of intellectualization and obsessiveness, often very useful to psychotic children, are promoted indirectly. The focus is on learning to live in the world.

The rationale for educational therapy is that the psychotic child, having irreversible personality defects, must develop those areas of function that are least damaged, namely the capacity to imitate, to respond to cues, to learn adaptive skills, and to live "as if" he were a total person. The goals are in the main similar to those of psychotherapy. Although psychotherapy attempts to resolve the basis for psychotic withdrawal, educational therapy attempts to bypass it. The latter is generally emphasized for the more severely ill children or by those who feel that resolution of the psychosis is not possible. The results of all types of therapy with psychotic children are most often given in terms of the numbers who are able to attend schools subsequently. Using this criterion, educational therapy yields results comparable to or better than other forms of treatment. Whether this is done at the sacrifice of more total self-realization of the child has not been clarified.

Behavior Therapy

Behavior therapy, which is the application of principles derived from learning theory research to the modification of abnormal behavior, has its origins in two sources. One is the classical conditioning experiments of Pavlov, and the other is in various learning theories. Although clinical application to adults began a couple of decades ago, its systematic application to psychotic children is of relatively recent origin, the first reports of its use appearing around 1960.

The most commonly used clinical technique with psychotic children is free operant conditioning: the child has an alternative between courses of action that he controls by means of an operation or action. For example, if it is desired to teach a mute child to say a word, a desired reward is withheld from him until he says it. Each time he performs correctly, he is rewarded, which reinforces the learning. Much less commonly employed is the technique of aversive conditioning, whereby undesirable behavior, such as bizarre gestures, is followed by an unpleasant consequence, such as darkening of the room or even an electric shock.

Since the severely psychotic child has very few sources of gratification already in his experience that motivate him to utilize free operant conditioning, the use of this technique must be preceded by a careful

study of the child to discover ways of providing gratification and establishing controls. Food is by far the most commonly used reward. Other social rewards are physical contact, verbal praise and reassurance, reading, singing, playing music, and dancing.

This therapy rests on the theory that behavioral principles, reliably demonstrated in learning laboratories, are also applicable to managing, modifying, building, and maintaining the behavior of severely disturbed psychotic children. The basic concept on which this rests is that behavior, both normal and abnormal, is learned. Psychotic behavior is a learned reaction that was originally established as a barrier either against a hostile world or as a defense for an organism unable to cope with ordinary life experiences. The persistence of the behavior is maladaptive and prevents the individual from moving beyond his infantile survival needs. The psychotic symptoms are no longer necessary and, if eliminated, will enhance the child's use of environmental supports and thus bring him greater rewards in the form of social adaptation.

Behavior therapy has been used primarily with autistic children who have responded very poorly to all other methods of therapy. Since it is nonverbal and requires little or no conceptualization on the part of the child, it is particularly suitable for these children. Because autistic psychosis begins very early in life, giving the child a pathological behavioral repertoire by the time he emerges from infancy, he is deprived of the ordinary social reinforcements that normal children constantly receive as a feedback from their behavior. The autistic child's behavior may be self-reinforcing, as he may establish contact with the environment only by means of undesirable behavior. For example, because of his resistance to initiating contact, he may be ignored unless he screams.

Behavior therapy is seldom used as the sole therapeutic tool. It is usually combined with some form of psychotherapy, milieu therapy, or educational therapy. Its specific goal is the elimination of highly maladaptive target symptoms that prevent the child from deriving benefit from other forms of therapy or from life experiences. These target symptoms are the social behavior of psychotic children that serve to reinforce their isolation and regression, such as muteness, lack of eye contact, bizarre gestures or vocalizations, avoidance of human interaction, stereotyped behavior, temper tantrums, insistence on repetition, etc.

The use of behavior therapy with psychotic children is too new to evaluate results systematically. In addition, since behavior therapy is imbedded within other therapeutic modalities, it is difficult to separate results, except in terms of specific symptoms for short periods of time. Since behavior therapy has been tried with those children who have proved most resistant to any therapeutic intervention, goals must necessarily be limited. Some workers have reported successful long lasting symptomatic results. Others have reported vari-

able responses and a high rate of relapse. The question of whether the learned response can be transferred to another person without loss remains unanswered. It is also apparent that operant conditioning is best in strengthening existing behavior and less useful in initiating new behavior.

Treatment of Parents

The degree to which parents of psychotic children receive treatment and the type of treatment they receive depends on the theoretical orientation of the therapist treating their child.

Those psychiatrists who believe that pathological attitudes on the part of parents, especially mothers, play a large part in the genesis of the child's illness recommend direct psychotherapy or even psychoanalysis of the parents. Some of the pathological parental factors held responsible are the parent's distortion of reality and teaching of unreality, primitive destructive fears and wishes, unconscious need for a psychotic child, and inability to sense the child's needs or to exercise basic authority with him. Therapists with an organic theory of the origin of childhood psychosis recommend guidance of the parents in adjusting to their child's illness. Group therapy is often used to give parents the opportunity to cope with their reaction of confusion, anxiety, guilt, isolation, hostility, and helplessness. Parents can also be helped to mobilize community resources for their child's special needs.

Parents are also seen as an adjunct to the child's psychotherapy, providing information for the therapist or creating a home environment designed in accordance with specific therapeutic guidelines.

Family therapy, which has been increasingly used recently with psychotic children, provides the therapist with details and clarity of family interaction, the degree to which family members recognize mutual needs, the methods with which they communicate with one another, and their distortions of reality. For young autistic children, the family therapist can demonstrate to the parents how to relate and handle the child. He may interfere with the destructive and self-injuring behavior of the child; show expectation of response, conformity, and growth; or break the parental habit of treating the child as if he doesn't comprehend his surroundings.

42.3 BRAIN DISORDERS

MAURICE W. LAUFER, M.D.

The American Psychiatric Association (A.P.A.) classifications under the heading "disorders caused by or associated with impairment of brain tissue function" cover a number of categories of clinical importance. But there is need for more general consideration of what may contribute to the particular pattern of dysfunction displayed by a particular child.

One consideration is the nature of the cause. Another is the particular time in the child's development in which the etiological factor begins to operate and the duration of time in which it does so. Another aspect is the severity or degree of insult from the etiological factor involved. Another contributing variable is the general status of the child. This itself is a composite of genetic factors, the extent of the central nervous system involvement, and the efficiency of parental management and interaction. For example, a highly intelligent child who has benefited from good child-parent interactions may more readily find or respond to ways of coping with a specific learning disability than another child who is not so fortunate.

The degree and kind of disability presented by a

child with some form of cerebral dysfunction is highly dependent on parental reactions and expectations, the meaning of the child and his behavior for this set of parents, and the expectations of his sociocultural milieu. One pair of parents may derive gratification from a hyperactive, aggressive youngster, as indicating they have produced "a real boy"; another pair of parents may be overwhelmed by the same picture. A child with a specific learning disability may be reacted to more negatively in an upper middle class family than in a lower socioeconomic milieu.

Etiology

Consideration of this area may be distorted by the popular concept of "brain damage," implying the prime and invariable role of traumatic insult to the brain. Both theoretically and practically it seems more appropriate to consider three general categories, all of which may lead to the same syndromes. The first of these is *maldevelopment*, in which there is a structural deviation from the normal due to a variety of possible causes other than trauma. The second does indeed reflect actual *damage* to central nervous system structure being formed or already formed due to such factors as trauma, infection, hemorrhage, and hypoxia. The third is *malfunction* without known structural change—for instance, the results of insufficient stimulation or of excessive stimulation at significant points in development or the results of distortion in the child-parent interaction.

When components of any of these categories impinge on a developing brain and psyche, there may be a greater effect than in an adult. There seem to be critical periods for the development of various functions. If there is interference at one of these times, it may be very difficult for the function ever to be developed adequately. In addition, a child's development follows both a segmental and sequential plan; therefore, early interference may have a profound and ever increasing effect, since subsequent phases of development are distorted by what has previously gone awry.

However, in a developing organism an early insult may be overcome in several ways. One is by compensatory overdevelopment of other functions. Or, in accordance with the concepts of equipotentiality, an uninjured area may to some extent take over the role of the injured one. Or, in later phases of development, that which was deficient earlier may no longer be critical in terms of total functioning.

Prenatal causes of central nervous system dysfunction are metabolic, genetic, infectious, toxic, and psychogenic factors. Perinatal causes are prematurity, postmaturity, prolonged labor, rapid labor, abnormalities of presentation, induction of labor, accidents of labor, effects of medication, immunological incompatibility, and normal mechanics of labor. The item "normal mechanics of labor" is in recognition of the fact that there are significant stresses and strains on

TABLE I
Syndromes of Cerebral Dysfunction

Area	Clinical Manifestations
Neuromotor	Cerebral palsy
Neurosensory	Central blindness, deafness, anesthesia
Consciousness	Epilepsy
Communication	Dysphasias, aphasias
Intellectual	Mental retardation
Perception, association, conceptualization, expression	Specific learning disabilities
Object relations	Some forms or components of psychoses of childhood
Impulse control, motility	Hyperkinetic impulse disorder

the fetal passenger, even in a normal delivery, and that firstborn males seem particularly susceptible to developing sequelae.

Postnatal (to 5 years of age) causes are infections, injuries, medications, poisons, toxins, metabolic or vascular disturbances, psychogenic-environmental factors, neoplasms, and convulsive disorders. The item "psychogenic-environmental factors" suggests that disturbances of human relationship and inadequate, excessive, or distorted stimulation and human interaction may have an effect on the developing central nervous system and lead to the development of one of the syndromes of cerebral dysfunction.

Syndromes of Cerebral Dysfunction

In order to develop a conceptual overview of the possible distortions of cerebral function that may result from the causes just outlined, Denhoff et al. have advanced the concept of syndromes of cerebral dysfunction. These are possible but neither invariable nor inevitable results of aberrations of central nervous system function and are partly stylized constructs for the purposes of description and classification. There are many possible variations. The symptom picture in a given child is the final result of the organically based tendency toward a deviation of function and the way the child adapts to and compensates for this. The latter, in turn, is a composite of the child's ego strength, coping mechanisms, and state of child-parent equilibrium (see Table I).

These syndromes often occur in varying combinations. One syndrome may represent the major presenting area or complaint, and another may contribute a major disability. For instance, in both epilepsy and mental retardation, hyperkinetic impulse disorder may be a component of the patient's disability.

Several of these syndromes, such as mental retardation, disorders of communication, and psychoses of childhood, are treated elsewhere in this text and will not be dealt with in detail here.

Hyperkinetic impulse disorder. Hyperkinetic impulse disorder and specific learning disabilities are often grouped together under the headings of "minimal brain injury" or "minimal neurological impairment." The two syndromes often occur together, but they may be found separately.

The possible etiological factors or combination of factors are categorized above. The most recent and possibly most authoritative estimate of incidence has been given by Masland as occurring in from 5 to 10 per cent of the school population. Since various causative factors may occur in all categories of the population, the symptom pictures may be found in all classes. They are more common among the socioculturally deprived, but their impact may be greater in more intellectually oriented groups in the population.

Clinical description. Hyperkinetic impulse disorder may have its onset in the earliest days of life. It is particularly common in firstborn males. Since the new mother is apt to be tense, fearful of inadequacy as a female, and convinced that the newborn, in some mysterious and primitive way, can divine and affirm or deny her essential worth as woman and mother, their initial encounter is fraught with significance.

A newborn who is already afflicted with hyperkinetic impulse disorder may be unduly sensitive to stimuli and may respond in an undifferentiated, massive, aversive manner. This may call to mind Freud's concept that there is a boundary to the developing ego, or *Reitzschutz*, that protects a human organism against being overwhelmed by stimuli and that this is in some way deficient in these infants. When a mother picks up the infant preparatory to feeding and he stiffens, arches his back, spits, squalls, and thrashes in wild protest, to the frantic mother this may represent the awful confirmation of her secret dread—that she has been rejected by the baby as inadequate. Her subsequent attempts to force the baby to conform only stimulate further negative reactions in the baby and may lay the groundwork for an ambivalent but predominantly negative relationship.

Frequently the converse of this sequence occurs, and the child is unusually placid, limp, and floppy, sleeping much and developing slowly in the initial months.

It is more common, though, for the infant to be active in the crib, have a rapid developmental schedule, sleep little, and cry much past the traditional first 3 months of colic. The infant often gets out of the crib on his own very early, undissuaded by the parents' attempts to bar his exit. Once out of the crib and able to get about, the infant is apt to do so relentlessly, getting into everything and generally fingering, breaking, or disintegrating objects. As time goes on, his sphere of activity widens and rapidly encompasses yard, neighboring territory, and street.

The "toddler" phase scarcely exists but is replaced by a gallop. As he gets older, the mother of-

ten complains that his constant activity keeps him from sitting through a meal, other children complain that he can't play ball because he can't stay at his assigned base, fathers complain that they can't teach him to fish or to work with them, teachers complain that he can't stay still in line or sit still in his seat, and so it goes.

Although hyperactivity is one of the hallmarks of this state, it does not always mean that quantitatively the degree of activity is greater than that of other children, though this may be so. Rather, it may be that the activity is relatively continuous and not turned off in inappropriate situations, such as school or church. Hutt and Hutt showed that hyperkinetic children were far less likely than normal children to reduce their locomotor activity when their environment was structured by social limits.

Often coupled with hyperactivity is short attention span or ready distractibility, which may be better viewed as "involuntary." The child is unable, without great and conscious effort, to inhibit his response to any stimulus that comes along, regardless of appropriate meaning or significance. In addition, the child seems incapable of attending to more than one stimulus at a time.

As Hutt and Hutt suggested, the hyperkinetic child is a "short sampler," incapable of attending to any stimulus for more than 10 seconds because of his rapid decay of memory traces. As soon as each stimulus has been explored, its central effects are lost, and the child comes back to it as if it were a fresh stimulus. Serial, repetitive sampling and monotonous, repetitive activity may be important learning and adaptive mechanisms for such children and may contribute to the apparently contradictory behavioral phenomenon of perseveration so often found.

Another set of phenomena, probably related, is impulsiveness and inability to delay gratification. The children are often accident-prone. In school, they may rapidly attack an exam and only do the first two questions, or they may rush quickly but inaccurately through all the questions. They may be unable to wait to be called on in school and may answer for everyone else, and at home they cannot be put off for even a minute.

They seem to have a need to handle and finger things, which often seem to disintegrate in the process. Hutt and Hutt pointed out that in these children, as in very young ones, the primary mode of contact between child and environment is by manipulation; they are seldom able to maintain visual fixations independently of manipulation; and they find it very hard to solve a problem visually before tackling it manually.

The children are often explosively irritable. This may be set off by relatively minor stimuli, and they themselves may seem puzzled and dismayed over this phenomenon. They are frequently emotionally labile,

easily set off to laughter and to tears, and their mood and performance are apt to be variable and unpredictable.

Not all the phenomena described are always seen together; there may be just one or two of these characteristics. Further, each item of behavior is often induced by difficulties in the emotional sphere, as in the child who is hyperactive and irritable as a result of inner tension and anxiety. But these behavioral phenomena may have their origin in altered central nervous system function as well as in emotional disturbance.

There are often other manifestations. Among these are a preoccupation with water play and a fascination with spinning objects. There may also be disturbances in left-right discrimination (internal and projected on the environment); in spatial orientation; in temporal orientation (internal time telling or clock time telling); in visual or auditory perception; in visuomotor performance and hand-eye coordination; in fine motor coordination; in figure-background discrimination; in the abilities to abstract, conceptualize, and generalize; and in the abilities to assimilate, retain, and recall.

Concomitant emotional difficulties are frequent. The fact that other children grow out of this kind of behavior and that the hyperkinetic does not grow out of it at the same time and rate, the variability of performance, the temporary response to pressures, the fact that in most cases the child is not retarded and therefore "has no excuse for his behavior," the general nuisance value and inexplicability of the behavior—all may lead to adult dissatisfaction and pressures. The resulting negative self-concept and reactive hostility are worsened by the child's frequent recognition that he "isn't right inside."

The impaired functions are ego functions, and their poor performance may both create and worsen difficulties in a circular manner. Because of them, the child performs poorly and unacceptably, resulting in criticism and other pressures. The impaired ego may also make it harder for the child to tolerate and adapt to the feelings evoked in him by these pressures. Such children are prone to develop almost any kind of psychiatric disability in response to those special problems, the normal needs for adjustment required in the process of psychological-sexual-social maturation, and those that may be imposed by psychological difficulties within the parents. These children are definitely not immune to the development of true neurotic pictures, but Kurlander and Colodny have stressed that these children may present a superficially identical picture, which they class as "pseudoneurosis."

Mechanism. The basic underlying mechanism for the development of this hyperkinetic picture is not known. In the course of their development, hyperkinetic children outgrow this mode of behavior.

This may be connected with the interrelationship between the diencephalon, which probably is fully formed and in full functional integrity at birth, and the cortex, which is by no means fully formed at birth but continues to grow at least beyond the 5th year of life and possibly to adolescence. One set of theories has suggested a reverberating feedback type of circuit between cortex and diencephalon. This postulates that, as the cortex grows in mass, it is eventually able to exert greater influence and allow for the more organized, localized, and discriminating responses characteristic of growth and for the ability to inhibit, which is one characteristic of maturation. Other theories have stressed the role of the diencephalon as the rostral component of the reticular activating system and its possible role as a first stage sorting, routing, and patterning mechanism for impulses coming in from sensory receptors to the various higher levels of the central neuraxis.

It has been suggested that in the first few months after birth the newborn infant operates under a homeostatic principle that induces great discomfort when any tension accumulates, with a great need to discharge this tension and return to the previously undisturbed state. Dysfunction of the diencephalon could make the individual unusually sensitive to stimuli flooding in from both peripheral receptors and viscera. This could well make a young infant respond with greater than usual urgency to what might otherwise be regarded as a normal amount of tension coming from the usual organic sources, such as hunger or a full bladder, and be hypertonic, querulous, and irritable.

Others have proposed that the rostral portions of the reticular activating system are concerned with ability to respond differentially to stimuli, to inhibit, to establish, and to alter set—all of which seem important in the production of this syndrome.

Diagnosis. Diagnosis has many facets. Most important is the history, which may reveal factors thought to be of etiological significance and also the kind of behavioral characteristics that have been described.

A neurological exam may be negative or show a variety of soft signs. Strabismus, mild central facial weakness, and mixed dominance are common.

Archimedes spiral aftereffect testing may be part of the diagnostic evaluation. In this, the patient stares at a rotating disk on which a black and white spiral has been mounted. With abrupt cessation of the rotation, an afterimage is normally seen, with the illusion of either expansion or contraction of what is being looked at, depending on the direction in which the spiral had been rotating. This is the normal response and tends not to occur in children with cerebral dysfunction with cortical involvement.

Standard scalp electroencephalography (EEG), though often showing no abnormalities, may be use-

ful. Almost any kind of EEG abnormality may be seen, focal or generalized. Bioccipital slow waves or spike-wave complexes are fairly frequent.

A special form of electroencephalography has proved useful and also tends to support the concept of diencephalic involvement. It is an adaption of the photo-Metrazol threshold technique first described by Gastaut as "a clinical neurophysiological test which provides a method for the exploration of certain subcortical structures, among which the most important are those of diencephalon and most especially of the thalamus." The results of this test were given in quantitative form (the photo-Metrazol threshold) as the number of milligrams of pentylenetetrazol (Metrazol) per kilogram of body weight required to obtain a specified type of response clinically and in the EEG when the patient was exposed to the flickering of a stroboscope light within a certain range of frequencies. Gastaut presented evidence to show through both human and animal studies that a photo-Metrazol threshold that was lower than normal indicated damage to or dysfunction of the diencephalon.

Modifying this procedure by using only the appearance of a spike-wave burst in the EEG as the end point and also standardizing on a stroboscope frequency of 15 flashes per second, in children from 7 to 12 years, the normal threshold was established as 6.5 mg. or above, borderline abnormal was 5.1 to 6.4 mg., and less than 5.1 mg. was clearly abnormal.

A group of 50 children who were sufficiently disturbed behaviorally to require residential treatment was selected and divided into two subgroups. One group of 32 children presented the symptom picture of hyperkinetic impulse disorder; the other group of 18 children did not. In the group with hyperkinetic impulse disorder, the mean photo-Metrazol threshold was 4.54 mg. per kilogram. In the group without hyperkinetic impulse disorder, the mean photo-Metrazol threshold was 6.35 mg. per kilogram. Statistically, the difference between the means for the two groups was highly significant.

A further highly instructive finding was the effect of administration of amphetamines (found clinically efficacious in the hyperkinetic picture) on the photo-Metrazol threshold. In a group of hyperkinetics, the mean photo-Metrazol threshold when not receiving amphetamines was 4.8 mg. per kilogram; the same subjects, when receiving amphetamines, showed a mean threshold of 6.7 mg. per kilogram. Thus, the use of amphetamines resulted in a rise of the mean threshold from an abnormally low to a normal figure. The difference between these two means is statistically significant.

Psychological testing may also be of value. Children showing only the behavioral aspects of hyperactivity, distractibility, impulsiveness, and variability tended not to show classical organic signs but on projective testing manifested their characteristic be-

havior in having a flow of associations, contaminations, and inability to delay. In those who showed visual-perceptual difficulties, problems with spatial organization, and other phenomena suggesting cortical and diencephalic involvement, the classical test signs became common. These included performance scores markedly lower than verbal scores on the Wechsler test, impairments of various subtests, distortions shown in the Bender-Gestalt, and organic signs in the projective tests. These, incidentally, often improved, as did the photo-Metrazol threshold, when amphetamines were used.

Psychiatric examination, in addition to clarifying the particular defense mechanisms and conflicts, may suggest the presence of a basic, pervading, organically based anxiety alluded to by Kurlander and Colodny as "primary anxiety" and called "body anxiety" by others.

Treatment. The first requisite is that the physician communicate to both parent and child his concept of the underlying central nervous system aspect and the rationale for treatment. There are wide variations in the possible responses of all concerned—from relief, to indignation, to feelings that this must be something irreparable, to agonizing confirmation of the suspicion that something is different, to a conviction that this must mean being crazy. Opportunities must be provided for ventilation of such feelings. The physician must also give an indication of prognosis. It can be stated with confidence that the hyperkinetic syndrome of behavior will be outgrown—treated or untreated—when the child is between 12 and 18 years of age. As yet, there is no way of predicting for a given individual when this favorable outcome will occur. And this prediction applies with such certainty *only* to the hyperkinetic aspect and not necessarily to learning or emotional complications or sequelae.

Nonetheless, it is important that the hyperkinetic picture be treated without waiting for its eventual disappearance. The mode of treatment is pharmacological, but there is some disagreement as to which medications are most efficacious. In children, there tends to be a paradoxical effect of medications affecting the central nervous system in that sedatives tend to stimulate and stimulants, on the other hand, tend to diminish rather than increase hyperactivity and other components of the syndrome.

There has been extensive experience with the amphetamines, both dextrorotatory and racemic. Which of these forms will work best is quite unpredictable. In children under 6 years, the general range has been 1.25 mg. to 7.5 mg. of the dextrorotatory form, once daily after breakfast, and 2.5 to 15 mg. of the racemic form. For children over 6 years, these figures are doubled. In most cases, a single dose after breakfast is efficacious, but it may be necessary to add another dose during the course of the day or to substitute or combine with longer acting forms. The

dose thus determined needs to be reviewed at 6-month intervals. With maturation, the need may diminish, but with bodily growth it may increase.

With time, the need for the medication will vanish, and this point may be recognized in two different ways. One is that the discontinuance of the medication does not allow the return of hyperkinetic symptoms. The other is that, instead of reducing overactivity, the usual effects of amphetamine—that is, overstimulation—begin to appear.

In evaluating the efficacy of the medication, some possible distortions are to be noted. One is that both child and parents may expect, by some kind of magic, that *all* behavioral problems will be erased and that, if they do not, the medication is not worthwhile. Professionals, parents, and children alike need to keep in mind that emotionally determined problems will not be erased by these medications.

Another important side reaction is that, even if the hyperactivity was due to aberrant central nervous system function, in the course of time it may have become incorporated in the psychic and defensive structure of the child, so that chemical interference with this hyperactivity may evoke great anxiety within the child. Dealing with this requires careful and thoughtful exploration with the child.

Another medication that has been used with apparent success is methylphenidate hydrochloride (Ritalin) in high dosages. Various phenothiazines have been suggested as helpful. Most of these have seemed helpful predominantly where there is anxiety that may have been present before or that may have been stimulated by the abrupt cessation of hyperactivity, which had come to serve a defensive purpose. Particularly useful is thioridazine (Mellaril), 20 to 60 mg. daily.

Another occasionally helpful medication, one without the side effects of the amphetamines, is 2-dimethylaminoethanol, in doses of 100 to 300 mg. daily.

Although these medications may, in a most amazing and beneficial way, control the organically based hyperkinetic aspects, they do nothing directly for emotional ones. When the latter are minimal and purely secondary to the difficulties in accomplishment related to the hyperkinetic picture, they may rapidly vanish without specific treatment. However, as was indicated earlier, these children may be more susceptible than others to the development of significant emotional disturbance.

Stone suggested that there is a link between and a common reservoir for the energy systems of the psychic apparatus and the neural apparatus. If the latter is damaged, then compensatory mechanisms that are called into play require greater than usual energy. This, in turn, makes the psychic apparatus more vulnerable to emotional stress. Conversely, in an emotionally threatening situation, energy being mobilized for psychic defense results in a worsening of

the neurologically based dysfunction, as there is less energy available for the previously used compensatory mechanism. This accords with the frequent observation that the neurologically based dysfunctions worsen under conditions of psychic stress. Conversely, when psychological status is improved, as by psychotherapy, more energy is made available to the central nervous system, with concomitant improvement in the symptoms associated with cerebral dysfunction. The child with cerebral dysfunction not only often needs but can profit from psychotherapy and should not be barred from consideration for it, as has been the case in so many child guidance clinics.

Since anxiety is often tremendously high and the damaged ego impaired in its attempts to adapt to stimuli, the child attempts to control and structure his environment to ensure that sensory experiences are, as far as possible, minimal and predictable. This may result in what look like obsessional and ritualistic maneuvers. These, however, differ from the true neurotic obsession in that there is neither fixation at the anal-sadistic level nor ambivalence in object relationships. These children are capable of intense attachments and open expressions of love and hate. Sarvis suggested that they may defend themselves against an evil self-image and paranoid attitudes by identification with the aggressor, the mother, or extension of the mother in general. This may lead to a danger of characterological effeminacy and may be a hazard to boys with unresolved oedipal attachments to their mothers.

When the children are not only allowed but helped to structure their environment, their anxiety diminishes. Thus their parents and teachers need to set up a structure that is predictable and experiences of manageable intensity. This applies to the physical, temporal, and interpersonal environment alike and should be one of the major areas of work with the parents. It may range from informational aspects to an intensive casework approach in dealing with their feelings of guilt, bewilderment, and hostility. An almost universal requirement is to help the parents recognize that the fashionable permissiveness is not beneficial for these children. They also need to be helped to recognize that, despite their deficiencies in some areas, these children face the normal tasks of maturation and attendant problems, including the need to introject standards and to form a normal, flexible superego. Therefore, they do not benefit from exemption from the requirements and expectations applicable to other children.

Stone cautioned the therapist to be careful in his interpretations, to focus on the reduction of irrational anxiety and guilt, to counteract feelings of omnipotence, to neutralize projections, and to improve reality testing. The therapist may need to be more than usually active, serve as an auxiliary ego, help the patient recognize the areas of realistic de-

iciency, and work with him on means to overcome this problem.

Specific learning disability. Specific learning disability is frequently associated with hyperkinetic impulse disorder, though each may occur alone. Specific learning disability refers to an impairment of the ability to learn scholastically up to a level appropriate to the individual's intellectual endowment. It is due to some disorder of cerebral function, rather than being emotionally, intellectually, or socially determined. There are many possible reasons for impairment of learning ability, dealt with in detail in other sections of this book. It is only desired here to emphasize that abnormal cerebral function may in itself be a significant cause, possibly in 5 to 10 per cent of school children.

Acute and Chronic Brain Disorders

As cited in the A.P.A. classification, acute and chronic brain disorders tend to be characterized by impairments of orientation, memory, intellectual functions, judgment, and affect.

Syndromes associated with intracranial infections. In the acute phase of epidemic encephalitis, encephalitis lethargica, or Economo's disease, the children may be hyperactive, excited, anxious and apprehensive, or confused, with delirium and hallucinations. In the chronic phase, they may be completely uninhibited, aggressive and destructive in uncontrollable rages, sexually preoccupied, emotionally labile, selfish, and suspicious. They may be moody, have spells of crying, laughing, or screaming, and have hallucinations. Sometimes, but by no means always, there may be accompanying intellectual deterioration.

In St. Louis encephalitis, headaches, lethargy, and seizures are often noted in the acute phase, and irritability and changes in behavior such as described above are relatively uncommon in later phases.

Measles encephalitis seems to induce personality changes a number of years later in a relatively high proportion of children. Phenomena seen include hyperactivity, difficulties in concentration, ties, tantrums, emotional lability, pointless fabrications, and impairment of school performance, which may be associated with impairment of verbal abilities, confusion of figure-ground relationships, and perceptuomotor distortions.

Pertussis encephalopathy is a much less common complication, but in those who incur it, the late sequelae are apt to be severe. In addition to the usual hyperactive, unpredictable, impulsive, and destructive behavior, there may be disturbances of relationships and reality testing severe enough to be classed as prepsychotic or psychotic.

Case reports of infectious mononucleosis encephalitis, of influenzal encephalitis, and of mumps meningo-encephalitis in children are alike in suggesting a rela-

tive and remarkable freedom from significant psychiatric sequelae.

The meningitides are more likely to result in neurological and intellectual defects than in significant psychiatric residuals.

Syndromes associated with poisons or drugs. These are prominently represented by lead poisoning. In the acute phase, the symptoms may be predominantly neurological, with irritability, convulsions, and coma. Some studies have suggested that there may be a sociocultural aspect to the ingestion of lead-containing substances, reflecting lack of care and supervision and proper maternal training or a culturally derived habit of clay eating. Many authors stress that this behavior is purposeful, occurring in a setting of emotional disturbance and family tension. This may contribute to the emotional instability so common in the late sequelae of lead poisoning. Many children become markedly retarded. Others have lesser degrees of intellectual deficit but tend to be hyperactive and distractible and have visual-perceptual and visuomotor problems and specific learning disabilities. In one study, out of 20 children who had suffered lead poisoning in early life, only 1 was performing adequately in school.

Barbiturates may result in clouded sensorium, impaired judgment, and mental deterioration.

Amphetamines—along with barbiturates, alcohol, and agents such as lysergic acid diethylamide (LSD)—are being used increasingly by adolescents for alterations of mood, alertness, energy, and states of consciousness, which are their acute effects. In adults, depression and psychotic states have been described with continued use, and reports of similar results may be expected for adolescents.

Gasoline addiction, in the form of inhalation, deserves some attention. This, along with sniffing of tar, is something seen commonly but transiently in many young children. A few, however, become really addicted to it. In the acute phase, while sniffing, they may have hallucinations, auditory and visual, then become drowsy and lose consciousness. In the chronic phase, there are predominantly signs of neurological disability. It is interesting that one child who practiced this habit for 11 years showed no evidence of a chronic brain syndrome.

Glue sniffing—sniffing of tubes of plastic cement and airplane glue—was quite common in the early years of this decade but seems somewhat less prevalent now. The acute phase is characterized by euphoria, excitement, exhilaration, and altered body sensations. There may be neurological phenomena, such as ataxia, diplopia, tinnitus, drowsiness, stupor, and unconsciousness. In the subacute phase, there may be irritability, inattentiveness, and episodes of drowsiness and unconsciousness. There have not, as yet, been reports of chronic brain syndrome.

Medications given for therapeutic purposes may induce hallucinations.

Congenital syphilis. Formerly a frequent problem, congenital syphilis is much less so now. The now rarely seen juvenile general paresis may result in progressive mental deterioration. There may be apathy, forgetfulness, irritability, restlessness, night terrors, temper tantrums, and impulsive behavior, often antisocial. Less often than in adults, there may be euphoria, expansiveness, delusions, and hallucinations.

Disorders of growth, metabolism, and nutrition. Among the inborn errors of metabolism, phenylketonuria has been prominently mentioned as contributing to mental retardation. There has been an increasing number of observations of altered behavior, not only in those who are retarded but also in children who present the same metabolic defect but without significant retardation. They may have a dull, expressionless facies, be negativistic and apprehensive, and have speech disturbances. Others are reported to display striking psychotic behavior, manifested by withdrawal from reality, failure to relate to people, echolalia, and stereotyped, catatonic-like posturing. There may be loosening of associations, rambling, bizarre and disconnected, primary process type of thinking.

Another inborn error of metabolism said to evoke a psychotic picture is that of cystathioninuria.

Acute porphyria may be accompanied by confusion, irritability, restlessness, insomnia, delirium, and hallucinations.

Dietary deficiency—as of niacin in pellagra, of thiamine in beriberi, and of the very prevalent kwashiorkor in deprived areas of the world—may lead to apathy, increased irritability, and some degree of intellectual impairment.

Endocrine disturbances may have psychiatric complications. In diabetes mellitus, hypoglycemia associated with difficulties in establishment of insulin dosage is common and may result in confusion and irritability. Hyperthyroidism may cause tension, anxiety, irritability, and emotional instability.

Intracranial neoplasms. These are not so often associated with personality and behavior disorders in children as in adults. One form in which they are relatively common is that of craniopharyngioma, where there are apt to be mood swings, lassitude, inertia, sadness, hallucinations, and excitement.

It has been suggested that there is a characteristic difference in reaction between children suffering from cerebral and from cerebellar tumors. The latter are said to be generally sweet, cooperative, and alert, and the former are said to be irritable and uncooperative.

Other than these statements, most reviews suggest that there is nothing really specific about a child's reaction to an intracranial tumor. Regressive tendencies, emotional instability, irritability, anxiety, withdrawal, and learning difficulties seem to reflect the fact fundamentally that cerebral functioning is

impaired. This interferes with the child's ability to deal with emotional stresses already present and now intensified.

Familial dysautonomia. A central nervous condition, not a tumor, that evokes similar effects is that of familial dysautonomia. The behavioral picture resembles that of hyperkinetic impulse disorder, with marked body anxiety and many secondary emotional reactions in child and parents.

Syndromes associated with trauma. In the acute phase, the patient may be delirious, confused, and stuporous to comatose. But the sequelae are of more concern. In many respects, children may show a post-concussion syndrome that is very similar to that noted in adults and about which there is continuing argument as to how much is neurologically based and how much is psychologically based.

The children may display marked irritability, restlessness, difficulty in concentration, ready fatigability, emotional instability, headaches, vertigo, sensitivity to change in position and to lights, noise, and confusion. Some degree of amnesia is characteristically present, and there may be some degree of impairment of intellectual functioning. Withdrawal, aggressiveness, and enuresis are common. So are sleep disturbance and the persistent recurrence of anxiety dreams in which the real or fantasied circumstances of the accident are recapitulated.

Undoubtedly, there are important psychological aspects to this. Symbolically as well as factually, the head contains the organ of control, and injury to it raises the specter of loss of control, including fantasies of insanity. Children, like adults, who have had a head injury in circumstances beyond their control may feel and fear that nothing is safe and predictable and may generate tremendous anxiety on this account, especially since the parents were unable to protect against this trauma.

Children, however, have a special vulnerability. As they go through the various phases of psychosexual development, acculturation, and superego formation, almost every phase has components or potentials for ambivalent or straightforward hostile and aggressive feelings within the child. Because of the characteristics of childish and primary process thinking, it is common and almost inevitable that the child will react to the traumatic accident as punishment and retaliation for his unacceptable wishes and thoughts. He may not only fear repetition of this or similar incidents, because the underlying drives or wishes continue unabated, but fear this even more because of the reactive hostility generated by the trauma he has suffered.

The situation is often worsened by implicit parental prohibition against some catharsis and working through of the traumatic event and the child's feelings. So often, the parents, meeting their own needs but justifying their actions on the ground that the child shouldn't be reminded, forbid discussion of the

event and develop elaborate schemes for avoidance of it. This not only prevents abreaction but makes it an even more frightening and menacing event as far as the child is concerned. Thus, regardless of the as yet uncertain proportion or contribution of a neurological component, psychotherapy for the child and counseling for the parents are often indicated.

A complication of head injury, subdural hematoma is more apt to result in neurological and intellectual deficit than any significant psychiatric picture.

Epilepsy. Common to all the diverse manifestations of epilepsy is some alteration in the state of consciousness and some impairment of complete control of actions. Both aspects may have psychological implications for both the patient and significant others—parents, teachers, siblings, other children and their parents.

Regardless of the type of seizure, there is often a distortion of the body image and self-concept. Sometimes this appears as a vague generalized unease or feeling that something is wrong. Sometimes there is an amazing specificity and, even in cases where there has not been a clinical diagnosis of epilepsy as yet, the child may have a conviction of something being wrong in the head. Since the head is so heavily cathected as the organ of control and is often sexualized and endowed with phallic significance, this may lead to a child's view of himself as crazy, impotent, or out of control. This, in turn, may be responded to by aggressiveness, withdrawal, inability to learn, counterphobic mechanisms, and a vast variety of behaviors that either act out or deny these distorted views of himself.

Grand mal seizures. In the most common form of epilepsy, grand mal, the patient is generally thought to have no awareness or recollection of the seizure itself, though he may have some recollection of the aura, when one is present, and may react to it as a warning of impending death. Unless he has his seizures only in sleep, this is likely to mean that he may suddenly awaken to find himself bruised, soiled and wet, with bitten tongue, surrounded by a ring of curious and horrified onlookers. This is enough in itself to make him think there must be something horribly wrong with him. This feeling would certainly be intensified by the negative reactions, on up to actual ostracism, of teachers, playmates, and their parents. Although this type of reaction is fortunately diminishing with the spread of public information and understanding, it is by no means entirely absent today. This, too, creates or accentuates a poor self-image, with the kinds of psychological reactions previously indicated.

Special note must be made of the reactions of the parents. Very often, despite the spread of intellectual understanding, they react—consciously or unconsciously—to the presence of grand mal seizures as a curse and affliction, a punishment for them, ret-

tribution for some misdeed in act or thought. They anxiously search their past and that of their marital partner for what it was that might have brought this upon them—masturbation, sexual activity, disobedience or hostility to parents, hostility to siblings, tainted stock, and a whole host of malignant fantasies. With this, come ambivalent feelings toward the afflicted child—pity and anger.

One of the most common reactions is overprotection, sometimes, unfortunately, fostered by medical and other advisers. The parents may limit the child's range of activities in all sorts of ways "so that he won't hurt himself in a spell." A variant of this is to fail either to set limits for the child or to require performances from the child unlike those the same parents would set or require for their other children. Both these modes of overprotection are exceedingly damaging to the child. They confirm his view of himself as someone different and interfere with the process of socialization and internalization of controls, with obvious distortion of psychological development.

Petit mal seizures. The situation is not so drastic for the child with petit mal or its variants, but there are similarities. The child with petit mal, who has sudden lapses of consciousness, may find it inexplicable and distressing that he seems to have missed something the teacher was saying or that he is suddenly behind the others in what they are reading. A child with akinetic or myoclonic seizures may be tremendously disturbed over the fact that, while drying the dishes, he suddenly drops or hurls a dish—not just once but many times. The frequent anguished cry is: "What's the matter with me? I must be crazy!"

Seizures with behavioral alterations. There are seizure types in which alterations of behavior may be the outstanding symptomatic manifestation. First in prominence is the grouping of temporal lobe or psychomotor seizures. Here, the seizure may be characterized by automatisms and aggressive outbursts ranging from verbal expressions of rage to actual destruction or assault. Some patients with bilateral temporal lobe EEG abnormalities have been described as psychotic.

Scott and Kellaway gave a more precise account of the types of psychic phenomena that may be encountered in temporal lobe epilepsy. These include (1) hallucinations, generally reliving an emotionally charged experience; (2) perceptual illusions, temporary distortions of subjective relationships with surroundings; (3) change of emotional tone, most often fear, terror, or dread; (4) disorders of thought or language, arrest of thinking processes, aphasia, forced thoughts or words; and (5) automatisms, actions, simple to complex.

There have also been accounts of behavioral disorders in children who showed a temporal or occipital spike focus without any overt evidence of sei-

zures. These children could show a hyperkinetic picture or oscillations in behavior, difficulty in relating to others, withdrawal or hostile aggressive attacks, enuresis or nightmares, or poor school work and paroxysmal headaches.

Contrasted with this is the description by Goldensohn and Gold of prolonged episodes of behavioral disturbance, which seemed similar to temporal lobe epilepsy but which, in the EEG, showed only generalized and not temporal lobe abnormalities. These episodes lasted as long as 72 hours, with confusion, hostility, negativism, withdrawal, with or without automatisms, but with apparent retention of consciousness.

Another type of seizure is that described by Gibbs and Gibbs as "hypothalamic and thalamic epilepsy," with which they associate the 14 per second and 6 per second positive spike pattern in the EEG in the sleep state, with attacks of rage and antisocial and vicious behavior, including murder, as possible concomitants of such seizures.

Epileptic personality. Conflicting accounts as to the interseizure behavior of epileptics raise the often debated question of the epileptic personality, described variously as egocentric, sensitive, irritable, rigid, resistive, suspicious, and hostile. This is complicated by the problem of subclinical seizure activity. Many studies with depth intracerebral electrodes have shown that there may be abnormal subcortical electrical activity, even when the scalp or direct cortical electroencephalogram shows no abnormality whatsoever. Conceivably the behavior of an epileptic between overt seizures may reflect the effects of subclinical seizure activity. Then there is the contribution to the epileptic's behavior of his own adversely altered self-image and his reactions to the real or fantasied depreciation of him by others.

Some small part of what has been considered the epileptic personality may derive from the frequent concomitant presence of hyperkinetic impulse disorder. Many of the medications used to treat epilepsy tend to accentuate and make worse or even to precipitate the appearance of hyperkinetic impulse disorder. They may also unfavorably alter other behavioral characteristics, obtund the individual or make him more irritable, depressed, or suspicious and thus contribute to the stereotype of the epileptic personality.

The seizures themselves—particularly those that are severe, prolonged, and repeated—can cause or accentuate a process of cerebral deterioration and the development of a chronic brain syndrome. They can have a particularly potent effect in this direction when the epilepsy is of the organic or symptomatic type. There is, therefore, a predisposition toward a chronic brain syndrome to begin with.

Taking all these aspects together, the epileptic per-

sonality does not seem to be a necessary and typical accompaniment of convulsive disorder.

Intellectual effects. The problem of intellectual capacity and function is significant emotionally because of the stereotype of inevitable intellectual deterioration being associated with epilepsy and the reverberating impact this may have on significant adults and then the child. There may, indeed, be some interference with learning because of the frequent association of hyperkinetic impulse disorder and of specific learning disability. Clinical and subclinical seizures may hamper learning capacity. So may medications used to control the seizures. So may the child's emotional turmoil.

But with present day medications and methods, epileptics, excluding those whose epilepsy is originally due to a profound cerebral insult, have the same range of distribution of intellect as the general population. The efforts of public health educators and lay organizations to communicate this will help to reduce not only the misinformation but also some of the emotional hazards connected with epilepsy.

Emotional factors. The role of emotional factors in epilepsy—in precipitation and in treatment—is an area in which some rather sweeping statements have been made. Perhaps to counteract the thesis that an epileptic grand mal was a recapitulation of man's ancestral piscine struggle to get out of the water onto dry land, the hypothesis was offered that an epileptic seizure was an attempt on the part of the patient to dive back into the uterine existence from which he had been dispossessed. These both seem as fallacious as most sweeping generalizations. Bona fide epilepsy seems to require some biological, physicochemical abnormality or predisposition. Given this, stress—generalized or specific—may precipitate a particular seizure, which is not the same thing as causing the epilepsy. In a person who does not have the epileptic predisposition, a similar constellation of emotional stresses and psychological structure will be reacted to in ways other than the production of a seizure.

Nonetheless, emotional aspects are very important. The very existence of seizures may create highly important psychological difficulties. In turn, emotional conflicts may precipitate seizures. Next, in a setting of emotional disturbance, seizures may, symptomatically at least, diminish this. There are two possible mechanisms for this. One may be relatively physiological, in that the seizure may literally discharge tension. Another may be symbolic, because of the particular psychological meaning of the seizure to the child or significant adults—punishment, expiation, orgasm, death, resurrection, etc.

The important thing to note is that there is no single, classical, pathognomic constellation of psychodynamics, interrelationships, and family involvements that inevitably and invariably causes or results from epileptic seizures; there are, rather, a whole

host of special and different situations. Gottschalk has tried to find a common denominator. He has speculated that there is a blocking of any nonspecific drive or strong emotion from gratification or expression by either an internal autonomous inhibiting factor or an external agent or situation. When this occurs in children who have a lower seizure threshold and less mature and more primitive impulses and emotions than other children, they are apt to respond with seizures. In these mixed pictures, psychotherapy is of the utmost value, reduces the tendency toward seizures, speeds a favorable outcome, and diminishes the need for medication.

As a final grace note, one may refer to the phenomenon, shared by the idiots of whom Dostoevsky wrote and by the great Russian author himself, of deriving gratification from a seizure, so that some have found means to induce it. More common in retardates than in geniuses, it may be for some the equivalent of an orgasm; for others, it may be relief from a drab existence; for still others, it may be at least an end to the tormenting feelings building up as a prodrome to a seizure.

Suggested Cross References

Organic brain disorders are also described in Chapters 18, 19, 20, and 21 in Area F, which deals with the psychiatric disorders of adults. Chapter 10, on neurology, and Chapter 22, on mental retardation, also contain information relevant to this subject. Fundamental concepts of neuroanatomy and neuro-

physiology are presented in Sections 2.5 to 2.9 in Area B, on the basic behavioral sciences.

Chapter 43

Psychiatric Treatment of Children

43.1 INDIVIDUAL PSYCHOTHERAPY

SAUL I. HARRISON, M.D.

History

Reconstructing the history of psychotherapy for children is complicated by uncertainties in delineating the limits of what processes should be labeled psychotherapy. This difficulty is greater with child psychotherapy than with adult psychotherapy because of the superficial resemblance between some child psychotherapeutic techniques and many of the usual practices employed in rearing and educating children. As a consequence, there is a risk that something may be designated as psychotherapy not because of the nature of the process but as a consequence of the child's emotional disturbance and the professional's preference to consider his interventions to be psychotherapy, regardless of their substance.

Evidence of direct therapeutic contact with children prior to the 20th century is rare. Until this century, formal efforts to cope with emotional and mental disturbances in children generally took the form of advising the parents about alternate means of handling their children. The experts rarely confronted the child directly in an effort to alter his clinical course. A noteworthy exception was the celebrated efforts of the French otologist, Jean Marc Gaspard Itard in the latter part of the 18th century. Itard adopted Victor, a prepubertal boy who was assumed to have lived the bulk of his life as a savage with animals in the forests of Aveyron. Itard undertook to civilize and educate Victor in a manner that conceivably might be considered psychotherapy.

The modern era of child psychotherapy is generally thought to begin with Sigmund Freud's famous case report of little Hans, a 5-year-old phobic child. Though the approach employed with little Hans should unquestionably be labeled psychotherapy, it is of historical significance to note that it was the young patient's father, a physician, who, under Freud's direction, was the psychotherapist.

Sandor Ferenczi, in the 2nd decade of this century, reported the first attempt at direct psychoanalytic treatment of a child without the use of an intermediary, such as little Hans' father. Ferenczi found that the psychoanalytic method, as then used with adults, was not feasible with his young patient, who readily became bored with this approach and wanted to return to his toys.

It was only after it was recognized that a child's play could be considered a valid means of communication that child psychoanalysis was developed as a direct psychotherapeutic approach to the child. The central role of play in the development of modern child psychotherapy has been compared to the historical significance of hypnosis in adult psychiatry. Each has contributed considerably to the understanding of unconscious mental phenomena.

Women who had the advantage of experience with children as well as backgrounds in psychoanalysis devised the means of utilizing play in treating emotionally disturbed children without the use of an intermediary. Hermine von Hug-Hellmuth published the first such report 8 years after Ferenczi described his abortive attempt. The major credit, however, for the subsequent development of child psychoanalysis belongs to Anna Freud and Melanie Klein. Melanie Klein's theoretical assumptions about the similarity of the child's and the adult's personality structure were expressed in the development of a therapeutic technique that considered the child's free play as a substitute for the adult's free associations. Anna Freud, giving more credence to the child's inevitable dependence on his parents, evolved a different technique. As she has recently observed, the early days of child analysis were marked by a prestigious tendency to emphasize the similarity between the processes of analysis with children and adults. The principal differences recognized then were the absence in child analysis of free association and transference neuroses. In recent years, as the development of a transference neurosis has come to be considered the *sine qua non* of classical psychoanalysis, transference neuroses have been observed during the course of child analysis. Concurrently, there has been a paradoxical decrease in the insistence of child analysts

that there is no distinction between the processes of child and adult analysis.

In the United States, the development in the 1920's of the child guidance clinic movement under the aegis of the National Committee for Mental Hygiene and the Commonwealth Fund gave much impetus to widening the scope of child psychotherapy, enabling it to reach its current status in this country. Lawson Lowrey credits David Levy with giving the first report, never published, on play therapy at the 1925 meeting of the American Orthopsychiatric Association.

Types of Psychotherapy

Psychotherapy, regardless of the age of the patient, has evolved so that practitioners tend to think either that there are several different psychotherapies based on varying frames of reference or that there is only one psychotherapy with the potential for a variety of different emphases. In either event, psychotherapy can be classified in several ways, based on various features of the process.

A common frame of reference for classification is the global one, which takes into account the general aim and mode of the treatment resulting in supportive-suppressive-directive and expressive-exploratory-ventilative types of psychotherapy. Focusing on the therapist's attitude or the influence that he endeavors to exert, psychotherapy can be classified as being abreactive, interpretive, suggestive, persuasive, educative, etc. It is possible also to describe psychotherapy in terms of its depth, duration, and intensity. Emphasizing the theoretical concepts favored by the practitioner results in labeling therapy with eponyms such as Freudian, Kleinian, Rankian, and Rogerian.

Probably one of the most commonly used bases for classification of child therapy is the identification of the factor that is presumed to be the most helpful for the young patient. The history of psychotherapy has been punctuated by different factors or processes being emphasized at one time or another as the vitally essential element without which psychotherapy would not be effective. Suggestion, persuasive exhortation, and reassurance were the most prominent psychotherapeutic techniques prior to the ascendancy of psychoanalysis. In the infancy of psychoanalysis, symptomatic relief was attributed to the fact the patient had rediscovered a lost memory. Shortly thereafter abreaction, the release of dammed up emotions, was highlighted. With further development of psychoanalytic thinking, the emphasis shifted to modification of superego standards, identification with the therapist, development of increased emotional discipline in the working through process, the development of insight, and expansion of ego functioning.

Concurrently, there has been a waxing and waning of prominence accorded conditioning factors, such as motivating needs, stimulating cues, and the reinforce-

ment of reward and punishment. Similarly, improvement has been perceived as developing from a deconditioning process that may involve systematic desensitization or a manipulation of the therapeutic relationship so as to provide a corrective emotional experience.

Clearly, many of these factors overlap, and many are comparable with others, despite the fact that they are articulated in different conceptual frameworks. For example, subtle persuasion, operant conditioning, and fostering identification with the therapist probably entail similar processes. Efforts to attribute therapeutic progress with *all* patients to a single factor are unconvincing. It is likely that all the factors mentioned assume varying degrees of significance under different circumstances. Although none of these factors is specific for any particular age group, it is evident that with children the relationship and corrective emotional experiences exert a greater influence than they do with adults.

Isolating a single therapeutic element as the basis for classification is somewhat artificial, as each of these factors is present, in varying degrees, in every child psychotherapeutic undertaking. For example, there is no psychotherapy in which the relationship between therapist and patient is not a vital factor; yet child psychotherapists commonly talk of relationship therapy to describe a form of treatment in which a positive, friendly, helpful relationship is viewed as the primary if not the sole therapeutic ingredient. Probably one of the best examples of relationship therapy is found outside a clinical setting in the work of the Big Brother organization, highlighting again the difficulty encountered in drawing a fine line between psychotherapy and child-rearing and educational practices.

Remedial, educational, and patterning psychotherapy endeavor to teach new attitudes and patterns of behavior to children who persist in using immature and inefficient patterns. Often, though not invariably, these are presumed to be due to a maturational lag resulting from some organic deficit that is difficult to define.

Supportive psychotherapy is designed primarily to enable a youngster to cope with the emotional turmoil engendered by a crisis.

Release therapy, described initially by David Levy, facilitates the abreaction of pent up emotions. It is this factor in psychotherapy that is publicized in the popular news media, probably because it is easy for laymen to grasp the idea of a youngster deriving benefit from venting a feeling such as hostility in a play situation. Although abreaction is an aspect of almost all therapeutic undertakings, in release therapy the treatment situation is structured to encourage only this factor. It is indicated primarily for pre-school age children who are suffering from a distorted emotional reaction to an isolated trauma.

Psychotherapy with children is often psychoana-

lytically oriented, which means that it endeavors through the vehicle of self-understanding to enable the child to develop his potential further. This is accomplished by liberating for more constructive use the psychic energy that is presumed to be expended in defending against fantasied dangers. The child is generally unaware of these unreal dangers, his fear of them, and the psychological defenses he uses to avoid both the danger and the fear. With the awareness that psychoanalytically derived psychotherapy facilitates, the patient is in a position to evaluate the usefulness of his defensive maneuvers preparatory to relinquishing the unnecessary ones that constitute the symptoms of his emotional disturbance.

This is to be distinguished from child psychoanalysis, a more intensive treatment, in which the unconscious elements are interpreted systematically in the sequence of affect-defense-impulse. Under these circumstances, transference manifestations may mature to a full transference neurosis.

Though interpretation of dynamically relevant conflicts are emphasized in these psychoanalytic descriptions, this does not imply the absence of elements that have been the basis for naming other types of psychotherapies. Indeed, in all psychotherapy, the child should derive support from the consistently understanding and accepting relationship with the therapist, and varying degrees of remedial, educational guidance and emotional release are inevitably present.

Differences between Children and Adults

It is often assumed that therapy with children should consume less time than therapy with adults. Experience, however, does not confirm this expectation. This observation has been explained by a relative deficiency in children of many of the qualities that are prerequisites for successful psychotherapy.

For instance, a child typically begins psychotherapy because some adult in his environment has decided he should have it. As a consequence, one of the first tasks for the psychotherapist is stimulation of the child's motivation for treatment. In fact, children are often brought to psychotherapy not only against their wishes but also without the benefit of parental support because the parents may be blind to the child's needs and seek help only because of pressure from educational and legal agencies. Thus, the child in psychotherapy, in contrast to many adult patients who see advantages in getting well, may envision therapeutic change in terms of conforming to a disagreeable reality.

Furthermore, children tend to externalize internal conflicts in search of alloplastic adaptations. This causes the child's view of therapy to diverge from the therapist's. Although many adult patients anticipate solutions resulting from internal change, children find it difficult to conceive of doing anything other than altering an obstructing environment. It is inconceiv-

able to the passive masochistic boy, who is the constant butt of his schoolmates' teasing, to rectify this situation by altering his mode of handling his aggressive impulses rather than by controlling his tormentors. This view may be reinforced by parental agreement.

The tendency of children to immediately reenact their previous feelings in new situations facilitates the early appearance of spontaneous and global transference reactions that often prove troublesome. Concurrently, the eagerness that children have for new experiences, coupled with their natural developmental fluidity, tends to limit the intensity and therapeutic usefulness of subsequent transference developments.

Children have a limited capacity for self-observation, with the notable exception of some obsessive children who resemble adults in this ability. These obsessive children, however, isolate the vital emotional components. In the exploratory interpretative psychotherapies, development of a capacity for simultaneous emotional involvement and self-observation is most helpful. Only by means of identification with a trusted adult and in alliance with that adult are children able to approach such an ideal. Furthermore, the age appropriateness of primitive mechanisms such as denial, projection, and isolation hinders the process of working through, which relies on a patient's synthesizing and integrative capacities.

Though children compare unfavorably with adults in the above qualities that are generally considered desirable in therapy, they have the advantage of active maturational and developmental forces. The history of psychotherapy for children is punctuated by efforts to harness these assets and to overcome the liabilities cited above. Recognition of the importance of play constituted a major forward stride in these efforts.

Therapeutic Techniques

The playroom. Scott has discussed the structure, design, and furnishing of the playroom suitable for child psychotherapy. He favors Klein's suggestion that the number of toys be few, simple, and carefully selected, so as to facilitate communication of fantasy. This contrasts with Axline's view that a wide variety of playthings be available, so as to increase the range of feelings that the child may express. These contrasting recommendations have been attributed by Brody to differences in therapeutic methods. Axline tends to avoid interpretation, even of conscious ideas, whereas Klein, at the other extreme, recommended interpretation of unconscious content directly and quickly. In teaching a flexible technique emphasizing neither of these extremes, the author has observed that therapists tend to change their preferences in equipment as they accumulate experience and develop confidence in their ability. Inexperienced therapists seem to derive a sense of se-

curity from having a large variety of playthings available. They stock their playrooms, for example, with many competitive board games, which they subsequently regret because these games can be so absorbing that they readily serve the purposes of resistance to therapy.

Initial approach. There is no standard initial approach to children in psychotherapy. Variations are derived from perception of the child's needs and the therapist's individual style. The range extends from those in which the therapist directs the child's thought content and activity, as in release therapy and certain educational patterning techniques, to those exploratory methods in which the therapist endeavors to follow the child's lead. Even though the child determines the focus, it remains the therapist's responsibility to structure the situation. Encouraging a child to say whatever he wishes and to play freely, as the therapist does in exploratory psychotherapy, establishes a definite structure. The therapist has created an atmosphere in which he hopes to get to know all about the child. He may communicate to the child that it is not the therapist's task to get angry or to be pleased in response to what the child says or does but rather that he is in the business of understanding children. This does not mean that therapists do not react emotionally, but it assures the young patient that the therapist's personal feelings and standards are subordinate to his wish to understand the youngster.

A child whose disagreeable behavior has typically evoked a negative reaction from everyone may be threatened by this new apparently unconcerned person, the therapist. It may seem unbelievable to a child that a strange adult he is seeing only because of his bad behavior appears to like the child with no knowledge of him other than the bad behavior. The more benign the therapist's attitude, the more horrid are the punishments the child may fantasize. When this is the case, it is incumbent on the therapist to communicate his understanding of the child's apprehensions about the neutral therapeutic approach.

An inhibited, neurotic child who is the product of a rigid home and a highly organized school may experience mounting anxiety in response to the apparent absence of structure in the psychotherapeutic situation. From his superego-oriented view of the world, such a constricted child feels that the neutral therapeutic situation invites forbidden instinctual expression. Once again, the therapist's verbalization of his understanding of the child's anxiety helps to clear the air.

Nothing induces a child to participate in therapy so readily as the therapist's demonstrated understanding of him. This may take the form of clarifying the child's reaction to the therapeutic situation, as described above, or it may entail interpretation of affect and defense preparatory to subsequent interpretation of impulses. Experience has dictated that

such activity often precludes the necessity for the introductory phase that used to be considered a vital preparation for child analysis and other exploratory psychotherapies with children. This introductory phase involved risky devices, such as promising the child a cure, joining the child in criticism of his parents, courting the child's affections in all conceivable fashions, exaggerating the gravity of a symptom and thereby frightening the patient, making oneself interesting to and useful to the patient. Such methods are rarely used today except with extremely regressed and withdrawn children. The demonstration of understanding that has replaced these introductory maneuvers should not assume an aura of magical mind reading. Rather, it should convey to the child that the therapist knows something about emotionally disturbed children, that he likes to help them, and that he has great faith in the value of understanding.

Communication. Some children participate in play activities immediately and verbalize spontaneously without assistance from the therapist; others appear to require considerable help. Responsive to the child's apparent needs, the therapist assumes either a relatively passive, observing role or a more active, intervening one.

Children generally are not so verbal as adults, making it vital that the child therapist appreciate and accept the importance and value of nonverbal communication. The child's facial expressions, gestures, posture, and motility and the content, form, and configuration of his play and art may say more than his words. Adopting this attitude, of course, essentially reverses the value placed on language in adult communication.

Furthermore, the child therapist must be prepared to adjust to the varying connotations attached to the same words and phrases by people of different ages. One of the most striking examples is the word "why," probably the most commonly used word in psychotherapy with adults. As such, it is expressive of the therapist's effort to understand. Children, however, often seem to react to the question "Why?" as if it were an accusation. Thus, even if the child's capacity for abstract thinking is sufficiently mature to enable him to appreciate that the therapist is interested in determining causal relationships, the child may regard an evasive "Because" as a suitable response. In all likelihood, whenever the child was asked to explain his actions or thoughts in the past, the questioner was not so much interested in establishing causal relationships as he was in being assured that whatever questionable thing the child had said or done would not be repeated. To test this assertion, the reader should observe queries directed by parents to children as to *why* something was said or done. This question rarely, if ever, inquires about approved deeds or thoughts. It is phenomenal how infrequently children, whether emotionally disturbed or not, are exposed to an interest in the motivational

forces underlying *valued* thoughts and deeds. It is no wonder that sensitive children in psychotherapy automatically translate the word "why" into criticism and disapproval. The result is that the message sent by the therapist is not the same message that the child receives.

Therapeutic interventions. Therapeutic interventions with children encompass the same range as those employed with adults in psychotherapy. If one regards the amount of therapist activity as the basis for a continuum, at the lower end are the questions posed by the therapist regarding the patient's statements or behavior. Closely aligned is the process of clarification of the patient's manifest productions by means of questions, recapitulation, or reorganization. Next, there are exclamations and confrontations in which the therapist directs attention to some data of which the patient is cognizant but which the therapist thinks the patient should attend to at the time. Then there are interpretations designed to expand the patient's conscious awareness of himself by making explicit those elements that have previously been implicitly expressed in his thoughts, feelings, and behavior. Beyond interpretation, the therapist may offer the patient new information, information that is new because of the patient's lack of experience. At the most active end of the continuum, there is advising, counseling, and directing, designed to help the patient adopt a course of action or a conscious attitude.

There are, however, some vital differences in the ways these interventions are employed with children and adults. The probable fate of broad, open-ended questions is illustrated vividly by citing the book title *Where Did You Go? Out. What Did You Do? Nothing*. To avoid such responses and to encourage verbal and nonverbal associations, the child therapist needs to be far more specific, focusing his questions on what the child is just about ready to express. The best clues, of course, come from what the child has already communicated. In essence, the therapist asks the child to elaborate on what he has already said or done. The therapist should not sound as though he is quizzing the child and invading his privacy. The more the therapist can imply curiosity, not unlike that of another interested youngster, the greater the likelihood of fruitful response.

This apparent naiveté should be tempered with awareness of the risk of asking questions that may seem devious to the child, such as those to which the therapist obviously knows the answer. For example, if the therapist, in his initial contact with the child, inquires about the reasons for the consultation, the child, who assumes rightfully that his parents have already told the therapist, may wonder whether the therapist is being dishonest. It can make a great deal of difference to the child if the therapist states that he already knows the parents' reasons for consulting him but that he is interested in the child's ideas. Simi-

larly, the therapist who inquires as to what dolls are doing, in an effort to have the child elaborate on the fantasy underlying the doll play he is observing, will very likely get a minimal return, since, from the child's point of view, what the dolls were doing should be obvious to the therapist. It would be more productive for the therapist to make running comments describing the dolls' activities, like a television announcer at an athletic event. Under those circumstances, the child often responds by elaborating on the therapist's description, thereby facilitating the approach to the underlying fantasy.

Certain interventions that are vital with children are generally superfluous if not insulting to most adults. For example, to tell an adult who is consciously angry that he is angry would be a confrontation that could readily prove offensive to most adults. With an angry child, however, the same intervention may be a necessary interpretation of affect, inasmuch as everyone may know about the child's anger except the child himself. Also, there are many more occasions with children than with adults where clarification of misconceptions can be helpful.

Many psychotherapists are convinced that it is wise to deal with defenses and resistances before interpreting impulses. With children, however, there is an important exception to this general guideline: it is often unwise to undo the projection into play that is so characteristic of child therapy. Thus, when a child with adequate reality testing causes two dolls to fight, the therapist's running commentary might be limited to a description of the dolls' affect, namely, that the dolls are angry with one another. Though the displacement of the child's own feelings to one or both dolls may be obvious, it may be wisest to communicate about the anger without attributing it to the child, thereby dealing with the impulse without interpreting the defensive projection into play. Under these circumstances, projection is viewed as an age-appropriate, adaptive mechanism rather than as a pathological, defensive maneuver. If the therapist told the child that he had the dolls fight because of his own anger, the child's resistance and defensiveness might be increased to the extent that he would stop the activity, interrupting the communication. It is as if the therapist and the child with adequate ego strength have tacitly agreed to the significance of play without spelling it out specifically each time. Bornstein noted other disadvantages in interpreting play directly. Repeated interpretation of the symbolic meaning of play can impede the child's use of play in the service of the development of sublimations, since such interpretations may facilitate libidinalization of play.

Treating children whose ego functioning is so defective that they confuse play and reality calls for caution in dealing with impulses displaced in play. In such instances, the therapist may have to devote his efforts to educating the child about the distinction

between play and reality before it is judicious to deal with the content of the play. This type of educational intervention, however, is not supportive for those children who do not have difficulty in distinguishing fantasy and reality and who are generally alienated by such interventions. At the risk of oversimplification, it is comparable to the situation when the therapist interprets to an adult patient that he feels as though the therapist were his father. If the adult patient's ego functioning were borderline, the therapist might add, "And I am not your father." To add this comment with a patient whose reality testing is not impaired would not only be unnecessary but also insulting and clearly not therapeutic.

Children can derive ego strength out of any activity that produces gratification as a consequence of making progress in lieu of attention-seeking devices. The dependent child who, for instance, repeatedly states or shows that he cannot perform a simple task, such as putting his shoes on the wrong feet more frequently than is possible by chance, needs to discover that there can be more gratification in an accomplishment than in getting the assistance of an adult. Similarly, psychic growth is promoted by the development of internal controls rather than reliance on the adult's external controls and by deriving gratification from work as opposed to accomplishing the same tasks by cheating.

Parental involvement. Psychotherapy with children is distinguished by the necessity for parental involvement. This does not necessarily reflect parental culpability for the youngster's emotional difficulties; it is a factor of the child's dependent state.

In practice, there are varying degrees of parental involvement in child psychotherapy. With preschool age children, it is common for the entire psychotherapeutic effort to be directed toward the parents without any direct psychotherapy of the child. The rationale is that helping the parents results in environmental alterations that will be beneficial for the child.

At the other extreme, children can be seen in psychotherapy without any parental involvement beyond the payment of fees and perhaps transporting the child to the therapeutic sessions. Most therapists agree that only those relatively rare neurotic children who have reached the oedipal phase of development can sustain therapy by themselves. Even in such instances, however, the majority of practitioners prefer to maintain at least an informative alliance with the parents for the minimal purposes of transmitting information about the child.

Probably the most common arrangement is the one that has been stressed in child guidance clinics—that is, involving both child and parents in therapeutic relationships either with the same therapist or with different therapists. In recent years there have been efforts to shift the focus from the child as the

primary patient to the family as the patient. In such family therapy, all or selected members of the family are treated simultaneously as a group.

Confidentiality. Consideration of parental involvement highlights the important question of confidentiality in psychotherapy with children. There are advantages to creating an atmosphere in which the child can feel that his words and actions are viewed by the therapist as both serious and tentative. In other words, the child's communications do not bind him to a commitment; nevertheless, they are too important to be communicated to a third party without the patient's permission.

Ordinarily, such an attitude is conveyed implicitly and does not require explication. However, there are occasions when a child patient insists on discussing the issue of confidentiality. It is unwise, particularly with those children who are inclined to make an issue of it, to promise a child patient that the therapist will not tell parents what transpires in his therapeutic sessions. Though the therapist has no intention of disclosing such data to the patient's parents, the bulk of what children do and say in psychotherapy is common knowledge to the parents. Therefore, should the child be so motivated, it is easy for him to manipulate the situation so as to produce circumstantial evidence that the therapist has betrayed his confidence. Accordingly, if confidentiality requires specific discussion during treatment, the therapist is best advised not to go beyond indicating that he is not in the habit of telling parents what goes on in therapy, as his job is to understand children and to help them understand themselves.

It is important also to try to enlist the parents' cooperation in respecting the privacy of the child's therapeutic sessions. Needless to say, this is not always readily accomplished. Parents quite naturally are curious about what transpires and may be threatened by the therapist's apparently privileged position.

Theoretical Assumptions

Brody has characterized child psychotherapy as a "theoretical orphan." This refers to the fact that child psychotherapy does not have its own readily identifiable body of theory. Currently, three major theoretical systems underlie the bulk of child psychotherapeutic work: (1) psychoanalytic theories of the evolution and resolution of emotional disturbance, (2) social-learning-behavioral theories of psychopathology and treatment, and (3) developmental theories.

Psychoanalytic theory. Psychoanalytic theory conceives of exploratory psychotherapy, with patients of all ages, as working by reversing the evolution of psychopathological processes. The principal difference noted with advancing age is a sharpening distinction between psychogenetic and psychodynamic factors.

The younger the child, the more difficult it is to distinguish between genetic and dynamic forces.

The development of these psychopathological processes is usually thought to begin with certain experiences that have proved to be particularly significant to the patient and that have affected him adversely. The reason for this may reside in the nature of these experiences or their intensity or both. Their influence may have been exaggerated because of their occurrence in the early, impressionable years of the patient's life or under special emotional or physical circumstances that rendered him vulnerable. Though in one sense the experiences were real, in another sense they may have been misinterpreted or imagined. In any event, for the patient they were traumatic experiences that have caused unconscious complexes to which the patient reacted in a manner analogous to the body's organic reaction to irritating foreign bodies. Being inaccessible to conscious awareness, these unconscious elements escape rational adaptive maneuvers. They are subject instead to a pathological misuse of his adaptive and defensive mechanisms. The result is the development of distressing symptoms, character attitudes, or patterns of behavior that constitute emotional disturbance.

The therapist can design various therapeutic programs to interrupt this evolution. Expressive and exploratory psychotherapy facilitates a reversal of this evolution through a reenactment and desensitization of the traumatic events via free expression of thoughts and feelings in an interview-play situation. Ultimately, the therapist helps his patient understand the warded off fears, feelings, and wishes that have beset him. As the therapist leads the patient toward his goal, he helps him realize that he has been defending himself, points out the nature of these defenses and the reasons for these maneuvers.

Though the patient may have varying degrees of desire to learn about himself and thus gain conscious control over automatic processes, he invariably manifests resistances. These are paradoxical tendencies that oppose therapeutic progress. For instance, patients invariably manifest an inertia that is grounded in the fact that what has been repressed tends to remain forgotten and what has been repeating itself for years tends to perpetuate itself endlessly. Also, there are usually advantages, real or imagined, in remaining emotionally disturbed, and certain people, greatly burdened by conscience, develop a need to suffer, which opposes psychic health.

At the center of these resistances to treatment are the psychic functions that facilitate forgetting and repetition, which lead the patient to reexperience certain feelings out of context without recalling their relevancy. In the therapeutic setting, it is the therapist who becomes the object of these reexperienced thoughts, feelings, and reactions, known as transference. Their origins are found in the past and

in relation to other people, notably parents. In such transference, the therapist becomes the target of desires, love, hates, or suspicions that make sense only when viewed in terms of relationships the patient has experienced with other people. With the therapist's recognition that the patient misunderstands the relationship, he attempts to use these transferred reactions to discover the genesis of the patient's problems and to formulate interpretations that will help the patient understand his enigmatic stance. The goal of these interpretations is to enable the patient to increase conscious control over heretofore automatic mental processes. The desired result is a rearrangement of his personality structure and enhanced ability to realize his potential.

Whereas such an expressive-exploratory-interpretive approach seeks improvement via exposure and resolution of buried conflicts, suppressive-supportive-educative psychotherapy works in an opposite fashion, aiming to facilitate repression. Capitalizing on the patient's desire to please the therapist, the patient is encouraged to substitute new adaptive and defensive mechanisms. In this type of therapy, the therapist uses interpretations minimally, emphasizing suggestion, persuasion, exhortation, counseling, education, direction, advice, abreaction, environmental manipulation, intellectual review, gratification of the patient's current dependent needs, and similar supportive techniques.

Learning theories. Stimulated by developments in experimental psychology, several theories of learning that have relevance for all psychotherapeutic undertakings have been developed. Recently, they have received increased attention as the basis of an allegedly new therapeutic method, most commonly referred to as behavior therapy. Regardless of the type of treatment, however, the theoretical assumptions, derived primarily from laboratory experiments, assert that, since disturbed behavior is acquired, its evolution and treatment can be understood within the framework of established theories of learning, such as Hull's reinforcement theory, Pavlov's conditioned reflex theories, and Skinner's operant conditioning.

This may be summarized by citing Watson and Raynor's classical demonstration almost a half century ago of the development of a phobia in 11-month-old Albert. After determination that Albert was not afraid of furry objects and that he had had no previous experience with white rats, he was given a rat to play with. Whenever Albert made an overture to the animal, the experimenters made a loud noise. After a short period of time, Albert appeared fearful whenever he saw the white rat. This phobia then generalized to similar stimuli, such as white rabbits, cotton, and other furry objects. Albert's experimentally induced phobic reactions reportedly persisted several months later. This was not the invariable response of

all infants; some turned to scowl at the source of the noise while they continued playing with the animal. Four years later, Jones demonstrated that another infant who had been conditioned to fear furry objects could be relieved of the fear by means of both social imitation and direct reconditioning.

As a consequence of coupling such observations with clinical experience, concepts encompassing the learning and reinforcement of maladaptive behavior have always been implicit in the rationale underlying all child psychotherapy. Only recently, however, has there been a resurgence of interest outside the laboratory in behavioral techniques specifically designed to eliminate symptoms. Systematic symptom-oriented efforts to induce unlearning, inhibition, and extinction of maladaptive behavior by means of desensitization, operant conditioning, aversive conditioning, avoidance learning, etc., have been applied primarily to phobias, enuresis, sexual disorders, tics, and anxiety-tension states. Eysenck suggested that those treatment approaches that explicitly employ behavior in an effort to change habits ostensibly rooted in the nervous system should be designated behavior therapy and distinguished from psychotherapy, which employs psychological methods.

Developmental theories. Underlying child psychotherapy are a variety of psychosociobiological developmental schemata. The employment of this vital frame of reference distinguishes child psychotherapy from adult psychotherapy. It entails more than knowledge of age-appropriate behavior derived from studies, such as Gesell's descriptions of the morphology of behavior. It must encompass more than psychosexual development with ego psychological and sociocultural amendments. It extends beyond familiarity with Piaget's sequence of intellectual evolution as a basis for knowledge of the level of abstraction in which children of various ages may be expected to function. It is more than recognizing that children of various ages do not react to hunger, other frustrations, injury, illness, and death in some uniform fashion that resembles adult behavior but rather in ways that are characteristic of their stages of development.

Such information may be derived from a number of descriptions of child development; however, it is essential that it be supplemented by personal knowledge and observation of children, with the resultant view of the child as fluid instead of static, as a maturing and developing organism who is not complete. The child's personality must be viewed in the perspective of the interrelationships of his past, present, and future; the focus must be on questions of regression-progression and transience-permanence rather than only on static assessments, even if they are articulated in psychodynamic terms.

Special mention should be made of the developmental line, as Anna Freud conceptualizes it, from play to work. Children do not play solely for the

recreational purposes that adults prefer to attribute to their own games and sporting activities. Play serves a number of important purposes, such as facilitating the mastery of many of children's inevitable developmental crises through playful transformation of what was passively experienced into activity. As a consequence, play has been assigned a special position in child psychotherapy, as both a medium of communication and a means of sublimation.

Use of Psychotherapy

Indications for psychotherapy. The present level of knowledge does not permit the compilation of a meaningful list of the multifaceted indications for child psychotherapy. Existing diagnostic classifications cannot serve as the basis for such a list because of invariable deficiencies in nosological specificity and comprehensiveness. In general, psychotherapy is indicated for children with emotional disorders that appear to be sufficiently permanent to impede maturational and developmental forces. Psychotherapy may be indicated also when the child's development is not impeded but appears to be proceeding in such a fashion that he inevitably induces reactions in the environment that are considered pathogenic. Ordinarily, such disharmonies are dealt with by the child with his parents' assistance; however, when these efforts are persistently inadequate, psychotherapeutic intervention may be indicated.

Contraindications. Psychotherapy is contraindicated if the emotional disturbance is judged to be an intractable one that will not respond to treatment. This is an exceedingly difficult judgment but one that is essential, considering the marked excess of the demand for psychotherapy over its supply. Because the potential for error in such prognostic assessments is so great, therapists should bring to them both professional humility and a readiness to offer a trial of therapy. There are times when the essential factor in intractability is the therapist. Certain patients may elicit a reaction from one therapist that is a contraindication for psychotherapy with that therapist but not necessarily with another therapist.

Another contraindication is evidence that the therapeutic process will interfere with reparative forces. A difficult question is posed by evidence that the forces mobilized as a consequence of psychotherapy may have dire social or somatic effects. An example is the circumstance where psychotherapy may upset a shaky family equilibrium and cause more difficulty than the original problem posed.

Selection of the appropriate technique. Most contraindications to psychotherapy really relate to complications that are not so much absolute contraindications as they are factors that influence choice of the appropriate form of therapy for the particular child. Matching the child and his disturbance with a

specific treatment is a worthwhile goal that is difficult to achieve because of limited precision in diagnosis and uncertainty about the curative factors in psychotherapy. Clearly, there is no single, effective therapeutic element in treatment. Though therapists may attempt to predict in advance which factor will be the most influential, experience demonstrates that such predictions have limited reliability. Therapists need to guard against developing rigid preconceived ideas that will interfere with flexible sensitivity.

Certain elements in psychotherapy with specific children induce complications that militate against that particular variety of psychotherapy for that child. Many children, for instance, respond to a positive, constructive interaction with a neutral adult, thereby necessitating no more than relationship therapy. However, there are many instances where such treatment is so insufficient that it is contraindicated because its chance of success is so negligible.

With most neurotic children, a form of interpretive psychotherapy aimed at uncovering intrapsychic conflicts is indicated. However, if the youngster's ego functioning, particularly in the area of reality testing, is borderline, such an approach may prove to be so deleterious as to precipitate a frank psychotic adjustment. A minimal prerequisite for interpretation of the significance of doll play to a child is that the child appreciates that the doll play is different from real life. When the child's capacity for such reality testing is impaired, therapeutic interventions should be designed to strengthen this defective function. If, on the other hand, this function is not impaired, efforts aimed at strengthening a child's intact reality testing by helping him distinguish doll play from reality are insulting and not beneficial.

Though there are many hyperactive children, there is no standard psychotherapeutic approach to the child with this distressing symptom. If, for example, the hyperactivity seems to represent a means of expressing anxiety resulting from an intrapsychic conflict over aggression, one would be inclined to approach that child with interpretive psychotherapy, exposing the child's conflicts over aggression to rational scrutiny. On the other hand, if the hyperactivity is presumed to be due to organic processes, the therapist's primary task is to supply externally the controls that are lacking internally. This may require medication, regulation of the child's life, isolating him from distressing stimuli, and similar supportive, suppressive measures.

These markedly different approaches to hyperactivity are not interchangeable. Though regulating the life of the anxiously hyperactive child may result in relief of the symptom of hyperactivity, this is done by inducing passivity as a means of handling the unconscious aggression—in essence, a new handicap. Approaching the child who is hyperactive due to organicity with accurate interpretations of underlying

conflicts may be perceived by the child as increased stimulation, to which he will react with greater hyperactivity. It is not the underlying conflicts that are primarily pathogenic so much as the deficiency in internal controls.

The fact that symptomatic treatment may be beneficial requires no elaboration. However, symptomatic treatment is not invariably innocuous; there are times when it may be harmful. Consider the youngster with the symptom of reading retardation, secondary to underlying emotional factors, who does not respond to tutoring. The tutoring could result in more than a mere waste of effort if the child takes his failure to respond to these special efforts to be further evidence of his stupidity and hopelessness. Furthermore, such a symptomatic approach may be unwittingly repeating a pertinent trauma for the child.

Eight-year-old John was unable even to begin to learn the alphabet in his 3 years of schooling. Intensive tutoring only seemed to increase his resistance to learning. It was subsequently uncovered during the course of psychotherapy that John's sister, 3 years his senior, used to play school with him. During this game, which started when she was 5 and he was 2, she played the role of the teacher and he the pupil. His inability to learn the alphabet in this game prompted his 5-year-old teacher to be extremely punitive and threatening. She warned John repeatedly that he would never be permitted to go to school unless he learned. This game and these warnings persisted until John's entry into school, when he terminated the game. However, in reconstruction during the course of psychotherapy, it appeared that John's expectation of school had been such that he was sure he would hate it. Unconsciously, he was determined not to learn so that he would not be permitted entry into school. Only after these experiences and their resultant ideas and attitudes were uncovered and worked through was John able to dismiss them as inappropriate to his current situation and to benefit for the first time from tutoring. Until that point he had unconsciously viewed tutoring as a punishment that reinforced his determination not to learn from it.

Psychoanalytically derived individual psychotherapy is most effective for youngsters who have internal, self-sustaining, neurotic conflicts that have not originated earlier than the phallic stage of development and have resulted in circumscribed, ego-alien symptoms. Such expressive-exploratory-interpretive therapy is generally less helpful to those children whose disturbance has not caused them much immediate discomfort. Such syndromes are often a consequence of conflicts derived from prephallic phases, and the resulting disturbance tends to permeate the child's entire character structure. Psychoanalytically oriented therapy is least effective when the therapist cannot establish a therapeutic alliance with the child, as in the cases where there has been an arrest in ego development resulting in a diminished capacity for abstract thinking and the establishment of object relationships. When the capacity for object relationship is severely limited, as it is in extremely young children or older psychotic children, the treatment needs to be based on a foundation of need satisfaction. In

such instances it may be advantageous for the therapist to be the person who cares for the child.

Prognosis

One of the most complex issues in psychiatry is the assessment of change and determination of the factors responsible for the changes. Inevitably the number of variables is so great that all investigators are cautious in attributing change to any single factor, including psychotherapy.

The amount of time and energy invested in child psychotherapy seems to suggest that clinicians are convinced it is a worthwhile endeavor. As the patient cannot be used as his own control, it is never possible to state with absolute finality what would have happened had that particular patient not had the benefit of psychotherapy. Investigators who have attempted to survey the results of psychotherapy statistically have amassed data suggesting favorable results in 65 to 80 per cent of the cases. Neglecting momentarily the complex issue of the methodology involved in determining success, one is still left with the question as to what would have happened to these children had they not been exposed to psychotherapy. Comparisons have been attempted with different types of control groups, but none of these has been entirely satisfactory. In all these studies there are reasons to question the degree of success of the intensive efforts to select a control group of children with comparable prognoses who had received no therapy. Comparisons of the treated children with these questionable control groups generally fail to demonstrate that the treated patients obtained markedly better results than those who left treatment early or failed to continue after diagnostic study.

Illustrative of the additional difficulties in determining meaningful and measurable criteria of the outcome of psychotherapy is the fact that appearance of anxiety in a delinquent is generally considered a sign of improvement while a comparable result in a phobic youngster probably represents lack of progress. Although symptomatic considerations alone are an inadequate criterion of the results of psychotherapy, it can nevertheless be anticipated that a youngster with academic inhibitions will demonstrate a better academic performance as a consequence of successful psychotherapy. In contrast, an obsessive-compulsive youngster may demonstrate, after successful psychotherapy, that his academic performance has diminished.

Furthermore, different assessments by different clinicians of the same change in the same patient are common. The tightly controlled obsessive-compulsive patient who, during the course of therapy, demonstrates loosening of his thought processes may be considered by one clinician to be on a progressive road to eventual recovery, whereas another clinician could view this same patient as being on a regres-

sive road to a schizophrenic reaction. The only variables in such instances are the evaluators.

The methodological problems inherent in the evaluative process have proved so great that many investigators have shifted their focus from study of the results of psychotherapy to examining the process of psychotherapy. Temporarily, they are willing to sacrifice a global but imprecise overview in favor of a more intensive investigation of the changes taking place during the course of psychotherapy in an effort to isolate the factors responsible for these changes. Thus, it is not yet possible to articulate meaningfully the results of psychotherapy for a large number of cases. There are currently in progress what appear to be meticulous methodological studies, and these are to be encouraged.

Suggested Cross References

For further information regarding psychological treatment methods, the reader is referred to Chapter 34, which contains sections dealing with the therapeutic techniques mentioned in this section, namely psychoanalysis and psychotherapy (Section 34.1), family therapy (Section 34.8), and behavior therapy (Section 34.2). Theories of personality and psychopathology that underlie the conduct of psychotherapy are presented in Area C. For a more detailed discussion of child development see Section 38.2. For a more detailed discussion of learning theory, see Section 3.3.

43.2 GROUP THERAPY

IRVIN A. KRAFT, M.D.

History

Group psychotherapy of children originated in 1934, when Slavson began to work with latency age children in what he called activity group therapy. This and subsequent work differed from using children in common activities, such as scouting or group work, by there being a theory of personality and behavior on which were predicated certain actions of the leader in a deliberately designed situation. The children's behavior in the contrived staging of the group constituted their responses to treatment.

Activity group therapy laid the groundwork for further developments in the use of group psychotherapy with children and adolescents. It used classical psychoanalytic therapy consistently, as did play group psychotherapy, which was described in 1937. In the same year, Bender reported using groups in the treatment of children in a hospital ward. During the 1940's, investigators devised different methods to suit the usual age groupings of children, especially latency and adolescence. Techniques were tried for different settings, such as correctional institutions, public schools, hospitals, residential treatment facilities, and pediatric specialty clinics.

Basic Assumptions

The field of group psychotherapy presents a number of theoretical postures and variations of techniques. Client-centered psychotherapy, Adlerian concepts, and classical psychoanalytic principles have dominated the practice of group psychotherapy for children. Despite the particular theoretical background of the therapists, certain assumptions pervade their work. These include the unconscious, some constructs of the mind (such as ego), psychic determinism, and infantile sexuality.

Activity—such as play, gestures, and interactions—is based on inner fantasies of the child that seek expression and resolution in development, family transactions, and other aspects of growth-promoting adaptation. From these and other considerations, a therapist evolves an individualized treatment style that enables him to work comfortably with his patients.

Certain theoretical positions—such as an adoles-

cent's possession of weak self-identity, subjection to strong sexual urges, and action on them—could lead to a definite, concrete mode of thinking about group membership. In this circumstance, few therapists attempted adolescent groups with boys and girls together until Ackerman, in 1955, showed that sexual acting out need not occur. Subsequent efforts by others demonstrated that boys and girls could be treated effectively in groups at any age.

Age Groupings

The age and developmental stage of the child influenced the growth of group psychotherapy techniques more than perhaps any other factor. Since the standard diagnostic nomenclature for psychiatric disorders of childhood failed to describe adequately the disturbances in children, investigators tended to group children by age and nature of presenting difficulties. They also assumed that the verbalizations of children could not be utilized extensively much before puberty or adolescence, so that play and activity dominated techniques. Psychotic children and severe sexual deviates, such as homosexuals, seemed unsuitable to the groups. The grouping of children fell into about five categories. These categories were: (1) preschool and early school age, (2) late latency: ages 9 to 11, (3) pubertal: ages 12 and 13, (4) early adolescence: ages 13 and 14, and (5) middle adolescence through late adolescence: ages 14 to 17.

Preschool and early school age groups. Work with the preschool group is usually structured by the therapist by using a particular technique, such as puppets, or it is couched in terms of a permissive play atmosphere. In therapy with puppets, the children project onto the puppets their fantasies in a way not unlike ordinary play. The main value lies in the catharsis afforded the child, especially if he shows difficulty in expressing feelings. Here the group aids the child less by interaction with other members than by action with the puppets.

In play group psychotherapy, the emphasis rests on the interactional qualities of the children with each other and the therapist in the permissive playroom setting. Slavson stated that the therapist should be a woman who can allow the children to produce fantasies verbally and in play but who also can use active restraint when the children undergo excessive tension. The toys are the traditional ones used in individual play therapy, such as water, plasticene, a doll's house, and toy guns. The children use the toys to act out aggressive impulses and to relive with the group members and the therapist their home difficulties. The children catalyze each other and obtain libido-activating stimulation from this and their play materials. The therapist interprets a child to the group in the context of the transference to her and to other group members.

Ginott aims in group play therapy to effect basic changes in the child's intrapsychic equilibrium

through relationship, catharsis, insight, reality testing, and sublimation. The mechanism of identification affords the child major opportunities for therapeutic gain, as he identifies himself with other group members and the therapist. Since the individual child constitutes the focus of the treatment, little attention is given to the group as an entity in itself. Corresponding to ordinary play relationships of children, attachments to peers and toys and the formations of subgroups shift for each child.

Criteria for selection. The children selected for this group treatment procedure show in common a social hunger, the need to be like their peers and to be accepted by them. Usually the therapist excludes the child who has never realized a primary relationship, as with his mother, since individual psychotherapy could better help the child. Ginott also rejects children with murderous attitudes toward siblings, sociopathic children, those with perverse sexual experiences, habitual thieves, and extremely aggressive children. Usually the children selected include those with phobic reactions, effeminate boys, shy and withdrawn children, and children with primary behavior disorders.

Modifications of these criteria have been used by Speers and Lansing, who utilized group therapy for autistic children along with parent group therapy and art therapy. They began with four children under the age of 5 who showed reality withdrawal and severe disturbances in self-identity. Language deficits, lack of bowel and bladder control, severe sleeping and eating disturbances, and stereotyped behavior were prominent in these children. The investigators reported that these psychotic children can change in a group setting by obtaining rudimentary self-identity. The physical and psychological closeness of the group members panicked some of the children, but in time it helped them establish relationships. The group ego, originally described for older children in group therapy by E. J. Anthony, provided part of a therapeutic symbiosis for each patient and developed after the autistic defenses were repeatedly penetrated. Safety in the group fostered emancipation from the sick relationship with the mother.

Latency age groups. Activity-interview group psychotherapy combines elements of activity, play, and interview group therapies. It differs from activity group therapy in that the therapist actively interprets to the children their actions and verbalizations as they involve themselves with the usual materials used in play therapy and activity therapy.

The children can be more disturbed than in activity group therapy, since dreams and other dynamically laden verbalizations undergo group discussion. The meetings occur after school hours and last about an hour, with the last 10 minutes devoted to refreshments.

In this type of group therapy, as with pubertal and adolescent groups, the children verbalize in a

problem-oriented manner with the awareness that problems brought them together and that the group aims to change them. They report dreams, fantasies, day-dreams, traumatic and unpleasant experiences. These and their group behavior undergo open discussion.

Composition of the group. In some clinic and private practice situations, where an activity therapy setting may not be feasible, the emphasis in the group treatment of these children can be shifted to an interview type with little toy play and no use made of tools or arts and crafts. Late latency age children (ages 9 to 11), who usually constitute the majority of referrals to a child psychiatric clinic, utilize this procedure well. The children can be of both sexes, and their selection depends more on the over-all structure of the group than on the individual patient's characteristics. The optimum size of the group is six children. If the group contains several withdrawn and taciturn members, for example, it behooves the leader not to include another similar child. The leader can be of either sex, and he utilizes psychodynamic generalizations in verbalizing with and for the children as they relate daily experiences and comments about their parents and discuss their interactions with other group members. Here, as in other forms of group psychotherapy of children, the professional discipline of the therapist may be any of the traditional ones in the mental health field. A cotherapist of the same or opposite sex to the therapist can be useful in these groups.

The patients not usually taken into these groups include the incorrigible or psychopathic child, the homicidal child, and the overt sexually deviant child. The severely threatened, ritualistic, socially peculiar children who cannot establish effective communication at any useful level with the group members fail to do well in these groups.

Intellectual ability should be well distributed, for too many retardates in the group impede interaction and tend to enhance motoric patterns of all the group members. Children with physical deformities, lies, protruding teeth, or behavior based on maturational brain dysfunction find the group situation helpful. Vehement interactions or taunts about their disabilities produce in time a group response of support as the members perceive the victim's sensitivities and feelings.

Since the sex ratio inherent in child psychiatric work with latency children runs 3:1 of boys to girls, finding enough girls becomes a problem for these groups. If possible, equal numbers of each sex should be sought. The girls act as a modulating influence and diminish extremes of behavior.

Parents. In these circumstances, as with most treatment procedures for children, parental difficulties present obstacles. Sometimes uncooperative parents refuse to bring a child or to participate in their own therapy. The extreme of this reveals itself when

severely disturbed parents use the child as their channel of communication to work out their own needs. Then the child finds himself in an intolerable position of receiving positive group experiences at the clinic that create havoc at home.

Pubertal groups. Similar group therapy methods can be used with pubertal children, who are often grouped monosexually rather than mixed. Their problems resemble those of late latency children, but they are also beginning, especially the girls, to feel the impact and pressures of early adolescence. In a way, these groups offer help during a transitional period.

Activity group psychotherapy has been the recommended type of group therapy for preadolescent children. The children, usually of the same sex and in groups of not more than eight, freely act out in a setting especially designed and planned for its physical and milieu characteristics. Slavson pictured the group as a substitute family in which the passive, neutral therapist becomes the surrogate for parents. The therapist moves about the group as the children work with arts and crafts materials and tools. He assumes different roles, mostly in a nonverbal manner, as each child interacts with him and the other group members.

This freedom of expression and activity instigates responses among the members so that a number of roles emerge. There are the instigators, who enable the group to stay alive dynamically; the neutralizers, who, by greater superegos, keep impulsive acts down and help regulate behavior; the social neuters, who seem impotent to accelerate or impede the flow of group activity; and the isolates, who are so neurotically constricted that they initially find the group too frightening to join in its activities.

These children use the materials, under some control by the therapist, as fixators of such feelings as aggression. They can, however, engage in boisterous and destructive acts, especially with each other. The therapist does not intervene except when realistic danger to the patient or building arises. He helps with tasks when asked. The method assumes that, in time, the children will constructively transfer their energy from the tools and materials to each other.

The refreshment period at the end of the 2-hour sessions affords the children stimulation by the food and a family type of situation in which new modalities of behavior eventually assert themselves. The children in this clublike atmosphere also go as groups on self-selected visits to a variety of community offerings, such as athletic events, movies, and museums.

Pattern changes. During these exposures to the group, the child demonstrates his customary and usual adaptational patterns. If, for example, he has utilized his haplessness to elicit dependency fostering and psychological feeding responses from adults and peers, he finds the group and the therapist failing him. The neutrality and passivity of the therapist impede

these patterns and create enough frustration to initiate different behavior in time. Similarly, the provocative, extremely aggressive child finds no rejection or punishment for his behavioral distortions. In time, he begins to react differently to the therapist and to his fellow group members.

The therapist needs to be consistently aware of himself and the individuality of each patient. He sees himself as a catalyst for each child in special situations at appropriately timed moments. All these demands confront the therapist with an intense need for appropriate use of himself and nonexploitation of the children.

This therapeutic medium helps children with deficient and distorted self-images, inadequate role identifications, habit and conduct problems, and mild psychoneuroses. Neurotic traits that may be present in behavior disorders diminish in this type of group. Characterological disorders—as shown by the passive, dependent, infantilized child—tend to alter as these personality traits persistently fail to achieve satisfaction and as other behaviors become possible.

Adolescent groups. Boys and girls tend to be divergent in social awareness and responsivity in early and middle adolescence. Nevertheless, with this in mind, the therapist can place them together in interview group psychotherapy. Ackerman described in 1955 his work with members who ranged from 15 to 23 years of age. Each patient had previously undergone individual psychotherapy, and his group therapy experience supplemented it. Ackerman suggested that the group functioned to "provide a social testing ground for the perceptions of self and relations to others." He emphasized the importance of nonverbal behavioral patterns as material for the group.

Subsequent reports tended to agree that group therapy dealt more with conscious and preconscious levels than did an intensive, deeply introspective approach. Hulse listed clarification, mutual support, facilitation of catharsis, reality testing, superego relaxation, and group integration as ego-supportive techniques.

Composition of the group. Adolescent patients can be treated in an out-patient clinic, private office, hospital, or a special setting, such as a detention home, with modifications appropriate to the setting. The group format is that of an open-ended, interview-interaction, activity organization. The preferred number of adolescents for these groups is 8 to 10, but often circumstances require screening of perhaps 30 or more to produce a group of 15. Of these, about 6 will form a core group with constant attendance and effort, another 3 or 4 will constitute an intermediate group who attend more than they miss, and the remainder will make up a peripheral group who attend occasionally. Attendance and therapeutic output are difficult to predict for the individual patient, since they do not seem to be related to age, present-

ing problem, and diagnosis. Some therapists suggest separation of patients in early adolescence (ages 13 and 14) from older patients, since boys of 13 and 14 find 17-year-old girls difficult to deal with in these groups. Otherwise, treatment procedures remain the same.

Here again, the diagnostic categories fail to distinguish sufficiently among patients to serve as guideposts to patient selection. Certain behavioral patterns—such as overt homosexuality, a flagrant sociopathic history, drug addiction, and psychosis—contraindicate inclusion in these groups. Group methods for these patients can be used, but they require special considerations.

Aims and techniques. Interview mixed group psychotherapy offers opportunity for the adolescent to learn peer-relating techniques in a protective and supportive situation. Diminution of anxiety over sexual feelings and consolidation of sexual identification occur. He participates in group interaction in time and feels the pull of group cohesiveness. He also reacts to the group's pace and its changes, as when the group shifts its content level, a phenomenon that occurs frequently and rapidly, often within a single session.

The adolescents employ diversionary tactics to avoid discussing threatening subjects. A favorite maneuver is to change the focus by a question or a comment about an unrelated topic. Sometimes diversion masks itself behind physical activity, such as throwing a gum wrapper at the wastebasket or showing a picture in a textbook to others. These and other behaviors frequently receive comments by group members; if not, the therapist calls attention to them.

Schulman, Kraft, and Duffy commented that the therapist must be active, ego-supportive, and in control of the group situation at all times. He interprets cautiously to avoid the patient's misconstruing interpretation as personal criticism. Interpretations also focus on reality rather than on symbolisms. They are couched in simple, direct references to basic feelings and to unconscious intent of behavior when it lies quite close to awareness.

The therapist can be of either sex. Coterapists and observers do not deter group movements and interaction. When the coterapists are of different sexes, differentiated responses to each occur.

The content of the discussions varies tremendously, ranging over school examinations, sibling competition, parental attitudes, difficulties with self-concepts, and sexual concerns. Sexual acting out or impulse eruption rarely occurs. Brief group responses to significant experiences narrated by a patient fulfill his needs, for he can return to the subject later if necessary. The group often prefers short discussions, since the anxiety is too high to dwell at length on a topic.

Therapy for delinquent adolescents. Since children and adolescents require many special care-

taking facilities by Western society, group psychotherapy techniques have been adapted to these different settings. Among these, the delinquent has received a good deal of attention, including group work, such as a field worker working directly with a neighborhood gang and group psychotherapy with probationers.

The customary procedures for group psychotherapy of disturbed adolescents require modification to account for contingencies of the character disorders of delinquents. These adolescents differ in their dys-social patterns from those who, in an adjustment reaction of adolescence or a transitional neurotic acting out incident, violate the legal, moral, and social values of the community. The adolescent with a delinquent character disorder is persistently truant, steals, runs away, or engages in other activities that usually mean removal to an institution.

Institutional group therapy. Schulman pointed out that the complexities of the interactional processes of group psychotherapy become complicated by the characterological pressures for dissent and chronic uncooperativeness. These factors and those inherent in institutional settings create design and procedural difficulties in studies to formulate the role of group psychotherapy for the antisocial adolescent delinquent.

Several reports indicate favorable aspects in this group. In Gersten's study in 1951 of group psychotherapy with male delinquents in an institution, he found that group psychotherapy improved intellectual and school functions, and psychological tests indicated some enhancement of emotional maturity. Another study reported by Thorpe and Smith in 1952 indicated sequential steps in the responses, the first being episodes of testing and the second a series of acceptance operations. Peck and Bellsmith in 1954 used group methods for delinquent adolescents with reading disabilities.

Schulman emphasized a 3-fold purpose in integrating group psychotherapy into the totality of care for these patients: (1) intellectual insight and reality testing occur in the group milieu; (2) alloplastic symptoms and superego development can be observed; and (3) the group situation readily tests the developmental stage of new attitudes, since the patient continues to perform in a homogenous group of delinquents.

The character distortions to be dealt with use aggression predominantly to reduce the internalized anxiety. The delinquents show a weak ego structure and a defective superego. Schulman suggested that their inherent difficulty with society and its authority symbols serves as the nidus for a therapeutic relationship. Modifications of the traditional therapist-patient relationship can then develop a shallow emotional attachment in the delinquent. Schulman initially used variations in activity and unexpected refreshments, but later he modified this to focus on the authority-dependency relationship built into the in-

stitutional situation. From the beginning, the adolescent knows that his getting out depends on the therapist, who then assumes a greater omnipotence and becomes one with whom he can identify. As the therapist continues to model early life experiences for the adolescent—but without their inconsistencies of feelings, exploitations, and dishonesties—he becomes somewhat of an ego-ideal for an embryonic superego.

Schulman and others described the sexual preoccupation of adolescent female delinquents and the need by the therapist to control it to avoid a deterioration through perseveration. This deterioration occurs in the male group also, often on a scapegoat in the group. Directed discussion by the therapist changes the tone of the session or blocks group disintegration.

Some therapists believe they can adhere to the more traditional leader role of permissiveness and support, contrary as it may be at times to the over-all patterns of the institution. The goals of all these efforts seem to fall into two categories. The first is to facilitate the delinquent's adjustment to the institution, and the second is to promote therapeutic readiness. Among the many variables that need to be examined, one of the most pertinent seems to be the duration of the group therapy process. Generally, the longer the group functions, the better are the chances for alterations in the members.

Other Group Therapy Situations

Some residential and day treatment units also use group therapy techniques in their work. Child placement agencies may use group psychotherapy with cottage parents, with the children, and with the foster parents employed by the agency. Unwed adolescent girls who have become pregnant have been placed in groups for counseling and psychotherapy. Children in pediatric hospital settings have been worked with in groups to help them handle their adaptation to disease and the hospitalization. Group therapy has been used in school settings for under-achievers, for truants, and for children with behavior disorders.

Children can also be treated by group methods in art therapy, and psychodrama has been used for children at all ages. Lebovici has described psychodrama for adolescents as providing as opportunity for action as preparatory for real life and a psychotherapeutic tool if used with the insights of psychoanalysis.

The foregoing has stayed mainly in the channel of group psychotherapy directly with the children. At the same time, most therapists agree that concomitant therapy with the parents is helpful. Some therapists believe that parental psychotherapy, such as a mothers' group, will be sufficient and more than adjunctive to remedying the problems with preschool through latency children. Multiple impact therapy can serve as both a diagnostic instrument and an intake de-

vice in family therapy. It is in these circumstances that one often sees so clearly how the child-patient can serve as the emotional radar of the family.

From the foregoing, one can gather that there are many indications for the use of group psychotherapy as a treatment modality. Some can be described as situational, where the therapist works in a reformatory setting in which group psychotherapy has seemed to reach the adolescents better than individual treatment. Another indication has been quoted as the economic one, as more patients can be reached simultaneously. Perhaps more appropriate would be the necessity to use a treatment procedure that will best help the child for a given age, developmental stage and type of problem. In the younger age group, the child's social hunger and his potential need for peer acceptance help determine his suitability for group therapy. Criteria for unsuitability are controversial. Ginott suggested that accelerated sexual drives or habitual thievery makes a child unsuitable for group therapy, but others disagree with him.

Evaluation

The results of group psychotherapy with children are difficult to evaluate. Several reports using control groups show favorable results in one study of nondirective play therapy and another of delinquents. Evaluating the results of group psychotherapy of children proves as difficult as assessing individual psychotherapy of children. Since few studies have been controlled for time as well as for other factors, including follow-up evaluations, one can say that group therapy does not supplant or replace individual therapy. It is another tool that the therapist might become familiar with by usage under supervision. If he then finds it to his liking, he can continue to use it under his own conditions of work. In crowded child psychiatric clinics, for example, various group techniques can help relieve pressures at intake, diagnosis, and treatment levels.

Impressionistically, certain results can be indicated. Group psychotherapy helps children feel unconditionally accepted by the therapist and the group members. Failures become seen as part of each child's development. Complexes of feelings and ideation gain expression. Feelings of guilt, anxiety, inferiority, and insecurity find relief. Affection and aggression are evidenced without retaliation and danger. In sum, group psychotherapy of children and adolescents still remains young and undeveloped in its full potential for study and treatment.

other measures if appropriate agents are chosen and the dosage is regulated properly. Drugs can then facilitate the educational and experiential aspects of treatment if the psychological meaning of the medication to children and their parents is treated with understanding.

Rationale and indications. With children, as with adults, one prescribes psychotropic drugs for certain target symptoms. Drugs are most effective in reducing psychomotor excitement. Optimally, the reduction of impulsivity and irritability is accompanied by lessened anxiety, improved attention span, and more organized behavior. To a lesser extent, drugs can increase spontaneous activity and affective responsiveness in states of apathy and inertia.

A trial of drug therapy is indicated for such symptoms if appropriate psychotherapeutic and environmental measures do not quickly relieve the child's subjective distress and restore optimal functioning. This judgment differs from adult therapy to the extent that children are more dependent on and responsive to the adults who care for them. One must evaluate the relation of the child and his symptoms to his family before introducing drugs. Since children's symptoms usually change more rapidly than do adults', one can often evaluate a child's response to ambulatory or institutional psychiatric treatment within 2 to 4 weeks.

If symptoms disappear completely, in the child's usual environment, with full resumption of social and academic activities, with the use of social manipulation and psychotherapy alone, obviously no additional treatment is indicated. However, if symptoms or a restriction in function persists after 4 weeks, one should not withhold drugs that may accelerate recovery because the child is responding slowly to other measures. Months or even weeks of exclusion from normal experiences at critical periods in a child's life may leave irreversible deficits. A school phobia is an outstanding example of a situation that should be treated as a medical emergency. A prompt return to school can prevent chronic disability, and drugs should be added quickly to the total treatment program if needed to accomplish this end. Even when the damage from delayed recovery is less obvious, one must weigh the slight chance of harm from drugs against the limitation in the child's function and the strain imposed on his family if drugs are withheld. If an acute crisis demands immediate medication, drugs should be withheld later on to evaluate the child's own capacity for reintegration and to determine whether medication must be continued.

Results and goals. Pharmacotherapy should be used as a part of the total treatment program directed toward promoting optimal development of the disturbed child. By modifying appropriate target symptoms, drugs facilitate the other aspects of therapy in children with schizophrenia and organic brain disease and with moderate to severe primary behavior

43.3 ORGANIC THERAPIES

BARBARA FISH, M.D.

Psychopharmacotherapy

Since 1940, amphetamines, anticonvulsants, and antihistamines have been used to treat children with behavior disorders. The introduction of chlorpromazine and reserpine increased the range of effective pharmacotherapy. Drugs are now as important an adjunct in the comprehensive treatment of disturbed children as they are in the treatment of adults. The fact that the child is a growing organism creates special problems in evaluating the effects of drugs.

However, experience has demonstrated that drugs can control symptoms that do not readily respond to

disorders. Pharmacotherapy may enable severely disturbed children to participate in group activities and special classes; it helps others become amenable to psychotherapy and education that would otherwise be impossible. Drug therapy can also accelerate the treatment of less disturbed children. For example, some neurotic children with persistent anxiety, inhibitions, and phobias become more spontaneous and increase their adaptive functioning, participating more fully in psychotherapy and schooling, if they are given drugs. The younger the child, the more often is psychiatric disturbance of any type expressed in hyperexcitability, hyperactivity, and disorganized behavior that can respond to medication.

Limitations. When drug-susceptible symptoms are treated, the extent of improvement in over-all psychopathology is limited by the initial severity of the disorder. The more severe, unchanging deficits in function appear to have the same prognostic significance in children as do long duration and chronicity of symptoms in adults.

Children with severe mental retardation and fragmentation of functioning, associated with organic brain disease or schizophrenia, are the most likely to retain residual defects. However, in the absence of effective drug treatment, they respond minimally to educational therapy, milieu therapy, and psychotherapy. In less impaired children, hallucinations, perceptual distortions, and thought disorders may subside or disappear with drug treatment.

Drugs can modify a child's responsiveness to his experiences, but chemicals alone cannot undo learned behavior, character patterns, or neurotic attitudes. Thus, aggressive behavior responds to drugs only if it is associated with affective or motor outbursts. Less explosive negativistic children often experience little subjective discomfort and may resent the physiological changes produced by drugs, feeling these to be a threat to their autonomy. Whether drugs can improve learning and intellectual functioning and, if so, in which types of children has still to be determined.

Choice and regulation of drugs. As with adults, pharmacotherapy with children should start with the mildest drug that may be effective. The dose should be increased regularly until symptoms disappear or until the first signs of excess dose appear (mild headache, fatigue, irritability, etc.), to make sure that the useful dose range has been fully explored. Young children rarely report such symptoms. One must ask and look for malaise, anorexia, weight loss, or sudden behavioral deterioration associated with increases in dose, which may indicate that the dose is too high for the particular child. The child's alertness, attention, and performance in school must be followed as carefully as the adult's performance on his job to determine whether the dose is insufficient or too high.

The child's response to medication may indicate

that a more sedative or more stimulating mild drug is required. Otherwise, one should explore more potent drugs in the same manner and not try a haphazard succession of drugs of similar type when symptoms persist with the highest tolerated dose of a mild drug. The optimal dose is the level that maximally reduces symptoms and increases function without causing discomfort.

In mild disorders, where symptoms disappear with mild medication, drugs need be continued only for a brief period, to give the child and his family sufficient time to establish a new level of adaptation in the absence of symptoms. In severely disturbed children who do not get complete relief from symptoms even with potent medication, pharmacotherapy may need to be maintained, just as it is with chronic adult patients.

In general, more potent drugs are required for more severe disorders, but the standard diagnostic categories provide only a gross guide to severity. In children, severity within a diagnostic group increases with greater intellectual, perceptual, and neurological impairment and with greater affective and motoric disturbance. Hyperactive and hypoactive children may react differently to drugs. There are also individual differences in relative sensitivity to the sedative and stimulating properties of different drugs.

The clinician should become familiar with a few representative minor and major tranquilizers and stimulants that span the spectrum of potency and differential effects. The following discussion is limited to instances in which children's behavioral and central nervous system responses differ from those of adults. The possible systemic toxic effects require the same precautions as for adults. Young infants require special precautions.

Major tranquilizers

Phenothiazines. Extensive experience has demonstrated that these compounds are highly effective in moderately to severely disturbed children with primary behavior disorders, schizophrenia, or organic brain disease.

Dimethylamine series. The major difference in action from adults is that extrapyramidal reactions are rare in children and can be terminated promptly by reducing the dose. The relative potency of different members within this group is the same for children as it is for adults.

Piperazine series. These drugs are especially useful in hypoactive schizophrenic or severely neurotic children who require drugs as potent as the phenothiazines but who tend to be depressed by therapeutic doses of chlorpromazine. Severely apathetic schizophrenic children with I.Q.'s under 70 may require and tolerate larger doses of trifluoperazine by body weight, compared with adult patients, without any signs of dystonia. If these children are very young and respond to the drug, their motor skills, social respon-

siveness, and language may improve. Fish et al. demonstrated that these effects were significantly greater than placebo in mute schizophrenic children who are too impaired to respond to psychotherapy.

Less impaired children tend to be more sensitive than adults to the stimulating effects of these drugs; small doses produce irritability, agitation, and dyskinesia. The adult dose adjusted strictly for body weight may be 2 to 5 times too high for such a child (see Tables I and II). Trifluoperazine (Stelazine) may be 20 to 100 times as potent as chlorpromazine in the same child in all but the most retarded schizophrenic children. Fluphenazine (Permitil, Prolixin) is more potent per unit dose than trifluoperazine. Prochlorperazine (Compazine), perphenazine (Trilafon), and thiopropazate (Dartal) are about 5 to 10 times as potent as chlorpromazine in the same child.

Piperidine series. Thioridazine (Mellaril) does not

^b Some children may require and tolerate higher doses.

appear to have any advantage for children over chlorpromazine that outweighs its additional systemic toxicity, since chlorpromazine-induced extrapyramidal symptoms are not a problem in children. Since mepazine (Pacatal) has a relatively high incidence of toxicity in adults, its use is not advised for children.

Rauwolfia alkaloids. These drugs have a less reliable action than the phenothiazines and are now generally reserved for severely schizophrenic children who have not responded to phenothiazines.

Minor tranquilizers. These drugs are primarily useful in mild to moderately severe neurotic and primary behavior disorders, comparable to their use in adults. The major difference from older patients is that children with moderately severe organic and schizophrenic reactions are frequently helped by certain of these mild medications. Prepuberty children, unlike adults and adolescents, do not tend to become addicted to medication.

Diphenylmethane derivatives. Diphenhydramine (Benadryl) is most effective in disorders associated with hyperactivity, but it also reduces anxiety in very young children who are not hyperactive. It may be helpful even in moderately severe organic or schizophrenic disorders, although it is not potent enough for the most severely disturbed children. Unlike the other drugs, diphenhydramine drops in effectiveness at puberty. Young children tolerate doses 2 to 4 times higher by body weight than do adults, and the drug reduces symptoms before producing drowsiness or lethargy. After 10 to 11 years of age, children respond like adults: the drug frequently produces malaise or drowsiness and is most helpful as a bedtime sedative (see Tables III and IV).

Substituted diols. Meprobamate (Equanil, Miltown) appears to be less effective for hyperactivity than diphenhydramine in the same subjects, but, unlike diphenhydramine, it continues to be effective in neurotic children into adolescence (see Tables III and IV).

Miscellaneous. Chlordiazepoxide (Librium) has a sedative action in some children comparable to the

most effective minor tranquilizers. In other children it stimulates speech and thought associations, like the amphetamines, but produces a more prominent euphoria. This effect is therapeutic for some depressed, hypochondriacal, and inhibited children. In susceptible children, however, this action is associated with toxic excitation and disorganization of thought and behavior before any therapeutic effect occurs (see Tables III and IV).

To date, the large number of other minor tranquilizers have shown no special actions that differentiate them from the three drugs described above; in fact, many appear to be weaker—even totally ineffective—and more variable in their action in the same patient.

Stimulants and antidepressants. Amphetamines relieve anxiety and inhibitions in neurotic children, especially those with constricted speech and affect, with learning difficulties, with school phobias, and with disturbing sexual preoccupations. Reports that doses up to 40 mg. a day quieted hyperactive children with organic brain disorders have not been confirmed by others who used a maximum of 20 mg. a day. Subjective discomfort, anorexia, and weight loss occur frequently in doses over 15 mg. a day (see Tables III and IV).

Antidepressants are indicated in the depressions of adolescence, comparable to their use in adults.

Anticonvulsants and hypnotics. Early reports of the effectiveness of hydantoin compounds in the treatment of children whose behavior disorders were associated with nonspecific electroencephalographic abnormalities have not been confirmed by later workers.

Hypnotics have not been demonstrated to be effective in psychiatric disorders of prepuberty children. Barbiturates may actually increase anxiety and disorganization in severely disturbed children. Chloral hydrate or mild tranquilizers usually suffice as nighttime sedation, unless insomnia is associated with a severe disorder requiring major tranquilizers.

Pharmacotherapy combined with psychotherapy. The use of drugs in conjunction with psychotherapy presents some differences from the treatment of adults. Young children generally accept medication in a matter-of-fact fashion as something doctors give to make them better. Adolescents tend to regard medication more suspiciously as an interference with their autonomy. This attitude requires the same sensitive and skillful handling as other aspects of adolescent therapy. Since children typically tend to deny physical and psychological difficulties, they are usually all too ready to terminate medication as soon as their distress is lessened. Seriously disturbed children who need maintenance drug therapy must be helped to understand that medication is to reduce their oversensitivity at the times in their life when this becomes necessary. Rarely, an older neurotic child may use medication in the interest of his hypochondriasis or to gain attention, and this psychologi-

cal problem must be resolved in psychotherapy. Parents should be told that, at best, drugs produce only quantitative changes and that the child will not be cured or made over. Discussions of all the other measures needed to help the child will emphasize this point.

The therapeutic meaning of biological measures, verbal interpretations, and environmental restrictions depends on the conscious and unconscious attitudes of all the participants. In the treatment of children, the parents' attitudes to medication and the other aspects of treatment must be dealt with as part of the therapeutic process. Drugs would destroy therapy if the doctor used them as a quick expedient to avoid responsibility for the child's complex problems in living or if he saw drugs as the ultimate weapon of authority to enforce compliance on a problem child or if he felt drugs were a measure of desperation to be used only after all other measures had failed. Children differ from adults only in that they are frequently more acutely aware of the doctor's unconscious intent and are less tolerant of his rationalizations. If drug therapy is put into its proper perspective by the physician, medication itself can then be accepted readily by parents and child as simply another way in which the doctor is trying to help the child.

Convulsive Therapy

In the United States, Lauretta Bender has had the most experience with this form of therapy in prepuberty children, having treated over 500 children since the early 1940's. She abandoned pentylenetetrazol (Metrazol) treatment when electroconvulsive therapy (ECT) was introduced because the latter was technically simpler to administer. She uses a standard series of 20 ECT treatments, of 100 to 110 volts and 0.1-second duration, administered with a Reiter apparatus, without premedication.

Bender considers ECT to be a valuable adjunct in a comprehensive treatment program for schizophrenic children. She believes that it acts as a nonspecific physiological stimulant "to stimulate biological maturation, to pattern primitive embryonic plasticity, to mobilize anxiety in the apathetic autistic child and to reduce anxiety in the pseudo-neurotic child." She advises against combining ECT with phenothiazines, since the latter lower the convulsive threshold. Her studies reveal no detrimental effect on development. In Sweden, Annell has used insulin shock therapy for schizophrenic children with similar results.

Psychotic adolescents who require convulsive therapy are those who resemble their adult counterparts.

Lobotomy

Freeman, the foremost proponent of this procedure in adults, reported on 12 psychotic children under 14 years of age and noted that some decrease in excessive motor activity was observed but that "the results in children compare unfavorably with the results of psychosurgery in adults." In principle, the irreversible destruction of tissue in the growing brain is not recommended.

Suggested Cross References

For further information regarding the organic treatment modalities used in psychiatry, see Chapter 35, which contains sections dealing with tranquilizers (Section 35.1), antidepressants (Section 35.2), electroconvulsive treatment (Section 35.5), and lobotomy (Section 35.8). Fundamental concepts of psychopharmacology are discussed in Section 2.3. Application of the treatment methods discussed in this section to the various psychiatric disorders of children are described in the sections in this area dealing with the specific syndromes.

43.4 RESIDENTIAL TREATMENT

MEYER SONIS, M.D.

During the past decade increasing attention has been focused on the need for more residential centers to provide a specialized program for children with behavioral symptoms not amenable to out-patient psychiatric care. Under the pressure of this need, it has been assumed that there is greater uniformity in such specialized facilities than is the case. A lack of uniformity exists not only in terms of which child is best served by which facility, but also in terms of the pattern of organization, administration, staffing, and programs to be found in these institutions. Such a lack of uniformity is not a criticism of the residential treatment center but is best viewed as a symptom of the historical evolution of the facilities.

This history is intertwined with the evolution of concern about children and their care and with the evolution of clinical knowledge of the psychiatric disorders of children. Residential treatment centers are the result of attempts in Europe and America to view the child as separate from the adult and to resolve the social, medical, ethical, and educational problems of the child who has deviated in his development.

History

Early history. For centuries in Europe, the only consistent concern and care for the poor and neglected children and adults was manifested through the auspices of the church. In 1267 A.D., for example, English law penalized the guardian of a child for waste but did not require his accountability for any child abuse. Until the Poor Law of 1601 in England, there was no concept of governmental responsibility for the welfare of children. Prior to this, children were often imprisoned, abused, and exploited; by law they had no rights. The Poor Law established public responsibility for the support of the poor—within which group were to be found many children with physical, mental, and emotional handicaps—and brought about

the development of the institution called the poor house or almshouse. It was not until the amendments to this law in 1868 and 1889 that parental neglect of children became punishable as an offense, and authority was given to the State for removal of children from their parents for such an offense. Such removal, however, placed the child in a state of apprenticeship to others.

In this country the concept of public responsibility as evolved in England was carried over and modified in keeping with New World concepts and needs. Asylums and almshouses were established by the local authorities for those who could not work or who were too old, crippled, or insane. Though neglected, retarded, and emotionally disturbed children were sometimes cared for by benevolent citizens or the occasional orphanage of a church, most of these children were mixed with unfortunate adults in the almshouses.

In the 1800's, the emergence of the view of children as separate and distinct from adults manifested itself in a variety of ways: the establishment of specific hospitals geared to the special needs of children; the emergence of pediatrics as a medical specialty; the initial movement to organize institutions for delinquent children; the admission of children identified as mental retardates to institutions for custodial care; the nucleus of the future juvenile court; and the prominent emergence of private, voluntary children's aid societies. In the organization and development of these private voluntary societies, aimed at providing care for dependent and neglected children, is to be found one major root of the future residential treatment center. These private agencies, many of them under the auspices of various religious denominations, sprouted throughout the country and were administered by and through humanitarian citizen interest.

Many children were indiscriminately placed in one institution or another. In most if not all of these various settings, little time or effort was spent in assessment of a child's particular needs. Behavioral symptoms as such in these children were of no interest unless such symptoms produced disciplinary problems for the institution. These children lived under rigid routines with moral and religious training predominant and without enough staff or funds or knowledge to attend to their needs. By 1900 many children, labeled as dependent and neglected or retarded, but with behavioral symptoms indicative of emotional disorders, were to be found in almshouses, orphanages, state hospitals, jails, training schools, and group homes. As yet, specialized programs and facilities for the disturbed child were not available.

Twentieth century. In the early 1900's several major developments took place, with each development playing a part in the formation of the other root of the future residential center. Social work evolved as a profession and brought with it the change of the trained layman to the professional. The contributions of psychoanalysis and psychobiology indicated

the importance of early child development and the environmental influences of child-rearing practices. The mental hygiene movement emerged and prepared the public for a more positive attitude toward the mentally ill and their need for specialized facilities. The child guidance movement flourished and brought with it specialized services for the child and the use of a team approach to the diagnosis and treatment of the emotionally disturbed child. The Children's Bureau, formed in 1912 as an arm of the federal government, drew attention at the national level to the needs of children.

As social work practice in the 1900's began using principles of social diagnosis and treatment and knowledge of programmed living for children, many of the private children's aid societies refined and changed their functions from the care, placement, and management of children to placement for the treatment of children. In many orphanages, group homes, and homes for dependent and neglected children, the well-intentioned laymen who wished to help children found their programs less effective for these children and increasingly required social workers to help them move toward professionalism in their programs. Some of these institutions, through experiences of their own and in association with social work, acquired skills of their own in the group care and management of children. They found, for example, that children maintained in a somewhat controlled setting were able to benefit from the warmth of available relationships. As the field of social work continued to develop, with emphasis now on the knowledge and skill necessary for planning and directing the daily lives of groups of children, the profession of social group work rapidly gained influence in many of the institutions providing care for dependent and neglected children.

The 1930's and 1940's. Perhaps the greatest impetus toward a change in these social agencies occurred in 1935 with the Social Security Act and its Aid to Dependent Children, which enabled many children, formerly seen as dependent and neglected children, to remain with their mothers. Increasingly, many of the agencies, formerly offering a group living program for dependent and neglected children, now found themselves with an increased number of referrals of disturbed children. Such agencies moved increasingly from their administrative base of volunteers and laymen to that of a professional staff, either totally or in part, depending on their former tradition. Many of these agencies, retaining their roots in social and religious orientation, acquired staff in response to these pressures. With a new emphasis on providing children with daily care while utilizing the environment to modify behavior, other professions joined the social work staff—social group workers, educational experts, recreational and occupational therapists, and psychiatrists. With this new emphasis on longer term growth processes for children, these agencies, through various

patterns of staffing and programming, began to provide for the child's total needs in terms of living, schooling, physical well-being, and recreation.

During that same period of time, as the social agency was evolving into a form of residential treatment center, the medical community was also undergoing change as a result of the developments influencing the social agency. The public and private psychiatric hospitals, whether state hospitals or institutions for defective children, had recognized the inappropriateness of their facilities for children and had expanded their function to include specialized wards for disturbed children. Parallel to this, in 1930, the first specialized facility was established for the study, diagnosis, and treatment of seriously disturbed children and their parents and was followed by many more of these psychiatric in-patient services. These specialized services were to provide a program of treatment based on a comprehensive diagnosis and were established as part of a larger psychiatric hospital or on an independent basis.

Within these medical settings, often hospital-oriented, many problems and issues began to emerge as the routine of the hospital ward and the structure of the traditional medical service was stretched to include the flexibility needed for child living as well as for patient care. In some settings, strong orientations emerged, leading either to a physiological bias in diagnosis and treatment or to a psychoanalytic bias in emphasizing individual dynamics. It became clear that knowledge of childhood psychopathology and the treatment of such were not enough and that more knowledge was necessary about using the environment as a tool in bringing about psychotherapeutic changes. In some of these treatment hospitals, much emphasis was placed on the utilization of the nurse as a therapeutic arm of the physician, but they discovered the need for greater flexibility and knowledge of children on her part. In some settings this issue of nursing care was managed by the requirement of specific training for child psychiatric nursing; in other settings the nurse was relieved of the daily care of children by development of nursing counselors, child care workers, or child aides.

In the early development of psychiatric hospitals for children, many children were referred to or dumped into these hospitals as a last resort, and in their acceptance by the hospital the children were literally disowned by the community. As a result, the hospital acquired a static population, and treatment programs reverted to custodial care. Some of the settings tended toward a concept of treatment biased heavily in a particular direction, depending on the orientation of its practitioners. There was a deemphasis of the original design of such centers to that of treatment based on a comprehensive diagnosis.

In the 1950's. By 1950, residential treatment of emotionally disturbed children had become loosely defined; it was a descriptive term that de-

pended greatly on the setting within which the service was offered.

In 1951 the Child Welfare League of America undertook a study of residential treatment of emotionally disturbed children. The report of their results stated: "From the beginning it was apparent that any attempts to develop firm criteria or standards was definitely premature. Rather, it was believed that a description of differing methods of practice might serve eventually to furnish a yardstick against which deviations of sharp differences could be measured and evaluated."

In 1956, partly in response to the growing need for evolving uniform criteria regarding residential treatment centers, a Conference on Inpatient Psychiatric Treatment for Children was held under the auspices of the American Psychiatric Association and the American Academy of Child Psychiatry. Recognition was given to the fact that the in-patient treatment of children was as yet a new field of development, a field that reflected the "concepts and practices of child psychiatry, in itself a relatively new field." Recognition was also given to the many questions as yet unanswered, such as the role of the child care worker, the need for epidemiological studies, more valid data as to judgments on the use of residential treatment and its efficacy. In this conference, a definition of a children's psychiatric hospital or unit was agreed on, and uniform criteria of physical plant, location, costs, personnel, staff-patient ratio, and treatment processes were developed for such units. A children's psychiatric hospital or hospital unit was defined as "a medical facility established for the diagnosis and treatment of children suffering from psychiatric disorders in which the psychiatrist carries medical and corresponding legal responsibility for the diagnosis and treatment of the patient." It was further felt by the conference participants that "the use of the word hospital for the specific type of service under discussion will help the community recognize this service as one in a range of services, each having its own function."

Evolution to present status. The residential treatment center and its concept of residential treatment for disturbed children emerged from the roots of the social and welfare needs of children and the medical needs of children with behavioral symptoms. These roots can still be found in the residential treatment of children. In the evolution of these two main streams there can be no doubt of the various problems and issues that have positively or negatively influenced the residential treatment center and its current patterns of administration, organization, staffing, and programs.

In the residential treatment center that emerged from the orphanage, child care institution, or group foster home, the focus on the disturbed child emerged from concern for the dependent and neglected child. In many of these institutions, the tradition of humani-

tarian motives, of doing good for children, making up for their deprived backgrounds, and providing moral examples for them to follow became competitive with the principles of scientific rigor in diagnosis or professional practice and treatment. The concept that disturbed children needed more than love became difficult to accept or put into practice through an organized and designed program that was aimed at more than simply social adjustment. The issues of changing from a lay administrator, a program dependent on a voluntary staff of charitable interested citizens, and a staff who simply liked children to a professional organization were symptomatic of this evolution. In the evolution of the orphanage to a residential treatment center, much experience had been gained in the care of groups of children but little experience in utilizing the knowledge of individual children. Like Topsy, the orphanage just grew into a residential treatment center, adding staff as needs arose, changing patterns as pressures mounted, moving from tradition to knowledge—but always with the base of its operation in the root of a social or welfare agency.

On the other hand, the residential treatment center, taking root from the medical stream, grew consistently from the professional base of psychiatry as a clinical science. This growth was not without its problems—problems that arose as a result of the competition between the scientific rigor of medical tradition and structure and the needs of children as social organisms. The starched white uniform became a symbol of sterility and was changed as the hospital ward structure evolved into a home atmosphere. The knowledge of the individual children had to be balanced now with knowledge of group transactions, caring for groups of children, and professionalizing humanitarian motives. The child guidance plan, so useful in the out-patient treatment of children, had to be expanded to include the teacher, the nurse, the nurse-counselor, the child care worker, the dietitian, the maintenance staff—but in such a way as to have the environment become a therapeutic force to support individual psychotherapy.

Types of Residential Treatment Centers

At the present time, despite the previous attempts to develop uniformity of criteria and despite the pressing need for data comparability, it is difficult to estimate the number, types, similarities or differences in program, or efficacy of residential treatment centers with any degree of accuracy. For example, in the Child Welfare League Study of such centers in 1961 (Hylton), a list of 120 institutions offering some type of program for emotionally disturbed children was compiled, but of this number only 27 were eventually deemed suitable for study by the broad criteria established. Eliminated from this study, for example, were centers that were primarily school programs, group homes, units of mental hospitals, and research units. In this same study, "to the best of their

knowledge, 4,600 children were in care at 80 residential treatment centers in 19 states."

Despite the heterogeneity of residential centers and within the limits imposed by the current reality of our knowledge, it is possible to present a profile of residential treatment and residential treatment centers as currently in practice.

Kinds of referrals. Of all referrals made to residential centers, only 15 to 20 per cent are accepted, with the majority of referrals not accepted, interestingly enough, on the basis that residential treatment is not indicated. Other reasons for nonacceptance of the referral are unavailable space, center policy, and inappropriate age. Most referrals to such centers are made by social and child welfare agencies, but this may depend on the auspices of the center; that is, the residential treatment center integral to a child psychiatric program may accept most of its referrals from within its own program. In a study of 1,000 children referred for residential treatment in New York State, "less than 25 per cent of the children have lived only in their natural homes, while 40 per cent of the children have lived in four or more homes or institutions, and three-fifths of the children did not have a continuous relationship with both natural parents."

Kinds of children. The majority of children served in residential centers are between the ages of 9 and 14, with the range between 5 and 17 years of age and with a ratio of more boys than girls. There are only a few centers available for adolescents at the present time.

The children served range from the child diagnosed as psychotic to the child with an adjustment reaction of childhood or adolescence; very few are diagnosed as having a chronic brain syndrome or as suffering from mental retardation. Studies have suggested that the spread of diagnostic categories in various residential centers indicates a random selection. It seems that this selection may be based on the nature of behavioral symptoms, the age of the child, the degree of parental alienation from the child, and the capacity of the institution to cope reasonably with the child. For example, in residential centers the child who is more aggressive, less difficult to reach, but more disoriented is often the younger child; the older child is less aggressive, more difficult to reach, and less disoriented. In other words, the residential center can cope more reasonably with the younger child who is severely disturbed and with the quieter adolescent. The average length of time that children remain in residence is about 2 years.

Kinds of institutions. Currently, if a profile were drawn of institutions within which the emotionally disturbed child is found and within which residential treatment is the service offered, the following patterns would emerge.

Placement units. These institutions, the numbers of which are impossible to ascertain, are under private

auspices and indirectly supported financially through contract for service with city, county, or state welfare departments. The institutions are thought of as providing treatment for emotionally disturbed children, but they are really providing group care, management, or custody, of a substandard nature, to the children in residence. These institutions are inadequately staffed, with an insufficient number of staff to provide a constructive program, and with most, if not all, of the staff untrained and ill equipped for the task. Many of the children in these institutions are there for placement purposes as a result of behavioral symptoms that have made them unmanageable in the community and have brought them to the attention of the courts and child welfare services. These children have seldom had the benefit of psychiatric examination and, if examined, would reveal extreme social pathology in addition to whatever psychopathology is present.

Residential center units. These institutions, the numbers of which are greater than the psychiatric in-patient units, are primarily under private auspices and financially supported through federated (Community Chest and various religious charities) and public (city, county, state, or welfare department contract for service) sources. These institutions are primarily under social work administration, direction, and practice. For emotionally disturbed children they offer a program of therapeutic care, complemented or supplemented by individual or group psychotherapy. In most of these institutions, the physical plant and program provide for almost all of the child's needs, such as living, schooling, routine medical care, recreation, and socialization. An adequate staff-child ratio is maintained to carry out the program. Some of these institutions utilize the community resources, if possible, for the education, recreation, and socialization of their children or for treating a child who requires hospitalization.

In these institutions, procedures and daily living are established in such a way as to involve staff members in meaningful opportunities for constructive interaction with the child. The professional and nonprofessional staff in such an institution covers the spectrum of social work, social group work, clinical psychology, activity group therapy, educational specialists, recreation staff, child care supervisor, child care worker, maintenance and kitchen staff, pediatrician, psychiatrist, art-drama teacher, dentist, and neurologist. In many of these institutions, the psychiatrist is utilized as a consultant—serving as a member of an admissions committee, supervising others in their psychotherapy of children and parents, or providing in-service training—or else he is employed as a staff member to provide psychiatric treatment for selected children.

Many of the children in these institutions are probably the least disturbed—severity of symptoms, intensity of behavior, diagnosis, chronicity—of all the

children in residential treatment centers. Most of these children are children of disturbed parents who have not been able to cope with the child.

Psychiatric in-patient units. These institutions are under psychiatric administration, direction, and practice. By design, organization, and procedures, they offer a program of psychiatric diagnosis and treatment of the emotionally disturbed child and a treatment regime that includes the daily care of the child. These institutions are under private, public, or university auspices and on the whole are integral to other child psychiatric services. They are utilized many times as a clinical facility for purposes of training in psychiatry and child psychiatry. Financial support of the institution depends on its auspices, with a source of funds similar to that of the residential treatment center.

As with the other residential treatment centers, these are self-sufficient in physical plant and program and provide for almost all the needs of children. In addition, they can provide more totally for the medical needs of the children within residence.

There are many similarities between these psychiatric in-patient units and the residential centers, but the differences are accentuated by the former's deliberate focus on a design of psychiatric diagnosis and treatment. This focus permeates the organization, program, staff philosophy, and goals. The nature of the organization as a psychiatric facility provides for the integration of all staff purposes under the leadership of the psychiatrist and with the basis of decisions about the child integral to therapeutic goals.

The children in these institutions are more disturbed than children ordinarily found in the residential centers. Their behavioral symptoms are more extreme, but they are manageable in such a setting. Since the psychiatric focus is basic, there is more opportunity for individual psychotherapy. For example, the Child Welfare League Study of 1961 stated, "The lowest child-psychiatrist ratios occur in the large psychiatric training centers, with ratios from almost two children per psychiatrist to seven; these same centers have the largest number of children in therapy with psychiatrists."

Since the ideal of involving all parents in active treatment cannot be carried out in practice, various patterns are developed to manage this issue, such as periodic 2- or 3-day visits of the parents, psychiatric or casework treatment of parents in their own community, and a policy of accepting only children whose parents are able to be involved in their regular treatment regime.

State hospital units. These institutions, under the auspices of a state mental health or hospital system, are under psychiatric administration and direction. Many offer programs of long term care and treatment of children with chronic psychiatric disabilities. The patient population of these institutions reflects this chronic disability in terms of diagnosis

(chronic brain syndrome, childhood schizophrenia, severe behavior disorders, mental retardation), age (more adolescents), social pathology, nature of behavioral symptoms (intense, severe, aggressive, chronic), and unavailability of community resources to these children previous to admission.

These institutions are also self-sufficient and provide for the total needs of children insofar as physical plant is concerned, but not in terms of total program. Most of these institutions have insufficient professional staff to carry out a program of total long term care and rehabilitation.

Problems

Of all the children descriptively diagnosed as emotionally disturbed and mentally ill, the children whose behavioral symptoms produce a guarded prognosis—controversial in terms of etiology and mode of treatment and yet severely in need of a comprehensive program of care and treatment—are also the children who face the problems produced by the evolutionary history of the residential treatment center. Problems for the child, mental health professionals, and community are not simply those of insufficient community facilities but also those of heterogeneity of definitions, approaches, ideologies, programs, methods, practices, and results. Problems have also been compounded by the community attitude toward the disturbed child.

A comprehensive exposition on the subject of residential treatment of children does not as yet exist, but fragments exist in the professional literature, studies published and unpublished, programs and conferences held, and the collective experiences of the various residential treatment centers. If an exposition were to present the relevant issues, it would of necessity have to include the problems of etiology, diagnosis, and treatment of the psychotic child; the differences and similarities between the child diagnosed as symbiotic, autistic, atypical, and schizophrenic; and the knowledge available for the diagnosis and treatment of the brain-damaged child. It should contain discussion of minimal brain damage, soft neurological signs, perceptual motor deficits, body image, developmental arrest, learning disability, and special sensory deprivation. Such a study should discuss the issues in the diagnosis and in the treatment regimen prescribed for children whose behavioral symptoms reflect child-rearing practices as well as neuronal disorders, genetic abnormalities, developmental phase, social pathology, psychopathology, nutritional imbalance, or parental disorder, or any combination of these.

In addition, such an exposition would include the various theories of child development, as this knowledge can be applied to the daily care of children; the difference between the practice of psychotherapy and social casework, care, and treatment; the education, training, and experience of the child care worker,

counselor, and therapist and their role differentiation; a discussion of medical-legal responsibility and its implication for the mental health and illness of children; the need for new laws governing child welfare practices and commitment procedures; and more answers to the many questions posed in 1956 by the Conference on Psychiatric Inpatient Treatment of Children.

Though such an exposition must await the further developments of the behavioral clinician and scientist, the past history of the residential treatment center does suggest the lessons to be learned from this history.

Use of Residential Treatment

Residential treatment has become a term synonymous with a therapeutic prescription for a child with behavioral symptoms that are indicative of serious pathology and prognosis, supported, maintained, or aggravated by the environment within which the child lives and an environment already suspect as an etiological agent. It is also a prescription for a child with symptoms not amenable to therapeutic intervention ordinarily available to the child while living in the environment but believed to be amenable to a treatment program offering: (1) separation of the child from this environment, (2) a corrective emotional experience through daily care, (3) an opportunity for the child to maximize his ability to make use of individual psychotherapy, and (4) an opportunity for the parents, now temporarily relieved of the child, to maximize their capacity to make use of psychological help.

The separation of the disturbed child from his environment can produce anxiety in the child that can be constructively used in his behalf if a physical environment can be made available for him to explore, manipulate, experiment with, and exploit. This environment should be one in which routines can be supplied as orientation for the child, not as imperatives of nature; one in which controls can be instituted to signal the limits of the environment and the limits of safety and to act as a comfort to the child when he fears abandonment while he probes the unknown.

This prescription can be an effective one to the extent that: (1) a comprehensive diagnosis is the basis of fitting the prescription to the child; (2) such a diagnosis also establishes the determinants of whether the child with behavioral symptoms can make use of separation as the therapeutic agent (placement), of separation and therapeutic care as the vehicle for change (residential center), of separation and therapeutic care as the entree for treatment (psychiatric in-patient unit), or of separation and controlled therapeutic care as the vehicle for psychiatric rehabilitation (state hospital); (3) residential treatment is integrated with the total range of clinical and non-clinical services available for the child with behav-

ioral symptoms, i.e., out-patient child psychiatric clinics, day care centers, acute service, specialized educational classes, foster and group homes with professional and semiprofessional staff, halfway houses, summer camps; and (4) the recommendation for residential treatment includes responsible plans for maintaining the relationship of the community to the child while the child is in residence.

ment centers are connected with hospitals, constituting one part of the range of services provided.

Therapeutic Factors

Milieu. Since the child spends a great part of his waking hours in the day treatment center, the establishment of a therapeutic climate is necessary to aid his rehabilitation, to enhance treatment, and to avoid antitherapeutic developments. Milieu embraces such factors as the degree and form of structure, the consistency of experience to which the child is exposed, the measures used to reduce anxiety and provide satisfactions, the management of undesirable behavior, the apportionment of the therapeutic responsibility among various staff members, and the staff attitudes toward one another.

Therapy. The emphasis that psychotherapy is given varies. Some centers see the operation as a framework for intensive psychotherapy; others view the milieu, opportunity for relationships, and removal from the home for a large part of the day, as the therapy itself. Psychotherapy within a center where the child necessarily relates to many adults in addition to his therapist, e.g., teachers, social workers, psychologists, aides, nurses, household and clerical staff, differs from psychotherapy that is temporally and geographically separated from the balance of the child's activities.

Therapists usually spend less time with the child than do other staff members, and therapists may not be present when significant situations occur. Therapy hours often compete with other scheduled events. Since the population in day centers is comprised of quite severely disturbed youngsters—largely psychotic, severe personality disorders, and chronic brain disorders—the ego-supporting therapies and pharmacotherapy are widely used. Therapeutic methods, such as the application of group techniques to the classroom, the use of individual teachers for corrective object relations, and emphasis on the "life space" interview, evolve from the special features of the day treatment center.

Education. In a day treatment program, school constitutes most of the child's day. Hence, there has been a close association between day treatment and special education of the emotionally disturbed child. Almost all day centers have an intramural school, since the regular school environment is one of the critical areas of failure for which children are referred. Because school can serve as a vital therapeutic instrument, the educational experience should be integrated into the total treatment plan.

The therapeutic value of coordinating education and therapy lies in the provision of a controlled environmental experience in which therapeutic gains can be reinforced, self-esteem and peer identification can be promoted, and techniques for coping with the environment and for developing useful defenses against impulses and anxiety can be provided. The school

43.5 DAY TREATMENT

RUTH L. LA VIETES, M.D.

Definition

Day treatment, sometimes termed day care or partial hospitalization, is that form of treatment in which the child spends the major part of the day in the treatment center, returning to his home for evenings and weekends. This method of therapy is relatively new, having been introduced in the early 1950's. It is designed to serve children who require more therapeutic intervention than is offered by a child guidance clinic but who need not be removed from their homes for residential therapy. Many day treat-

teacher, with her educational understanding of behavior, methods, and goals, should participate in the over-all treatment plan in order to utilize the therapeutic potential of the classroom and to avoid aggravation of the child's problems.

Treatment of parents. Since day treatment is predicated on the idea of children remaining in their homes, treatment of the parents is indispensable to obtaining optimum results. Parents of children disturbed enough to require day treatment have a high incidence of psychopathology, much of which interlocks with that of the child. The goal of therapy is the improvement of parental function and the reduction of the parental contribution to the child's illness, so that the child can remain in the home and sustain the gains achieved by treatment. Various forms of therapy are used—individual, group, joint, family.

Rationale

Day treatment is based on the assumption that children who would ordinarily be referred to residential centers are capable of achieving comparable gains while remaining in their homes. Helping a child within the home and community has the advantage of permitting simultaneous change in child and parents so that readaptation is facilitated. It avoids the anxiety and loss of self-esteem attendant on separation from the parents, the geographical distance that works against effective parental treatment, and the disadvantages of institutional living. The burden of management of the child is shared by the family, and the cost is lower than in residential institutions.

Indications and Contraindications

Day treatment is indicated for those children requiring long term treatment for an emotional disorder that has seriously impaired their social and academic adjustments. It is also useful as a transition between hospitalization or residential treatment and a complete return to the community. It is contraindicated for children who are homicidal or suicidal, who come from homes where responsible parental functions are not provided, or where parental psychopathology fosters the continuance of the child's illness or is too massive to permit the child's improvement within the home.

Goals and Results

The goals of day treatment are the return of the child to community facilities and the maintenance of gains. Only one study comparing the results of this mode of treatment with others dealing with similar groups of children has appeared. According to this report concerning schizophrenic children, those showing concomitant evidence of brain damage who came from normal families showed improvement comparable to that of controls in residential treatment. Nonorganic schizophrenic children, presumably having a larger re-

active factor in their illness, did better in residential treatment.

Suggested Cross References

More detailed descriptions of the therapeutic modalities mentioned in this section, such as psychotherapy and pharmacotherapy, may be found in Sections 43.1 and 43.3 in this chapter. General principles of psychiatric treatment are discussed in Area G. The problems of educating children with psychiatric disorders are discussed in Section 43.6.

43.6 PSYCHIATRY AND THE SCHOOL

RUTH L. LA VIETES, M.D.

Education is the process by which a culture prepares its young to assume an appropriate role in the social structure. Although this process begins at birth, in Western culture it begins to be transferred from the parents and the home environment into the formalized social institution of the school when the child is about 6 years of age. Readiness for formal education, as determined by law, is based on theories of neurological maturation and psychological development, that is, resolution of infantile family conflicts and achievement of latency.

Going to school is the child's first systematic separation from home and his first exposure to the administrative structure of society. The child must attempt to adjust to a strange adult and to a large peer group. He needs to perform tasks from which escape is difficult. His attitudes toward teachers, children, and work bridge the gap between his early experiences with parents and siblings and later experiences in adult life. The years a child spends in school influence his total personality, affecting the values he ascribes to himself, his relations to others, his potential for work productivity, and his life adaptation. School, therefore, offers a rich opportunity for the enhancement of mental health. School affects the total child population, cutting across all socioeconomic groups, with a captive attendance throughout childhood and adolescence, and with both a legal and a so-

cial hold on the child. School is committed to the welfare of children, providing the only compulsory professional contact between society and the child. Early detection of emotional disturbance and application of preventive measures are possible within this habitat of all children, and therapeutic measures can be undertaken in situ.

History

Problems of learning and manifestations of cerebral pathology have interested physicians for many years. Itard and Séguin studied mental retardation, and Montessori devised educational procedures for retarded and normal children, stressing sensory and cognitive development. However, the advent of psychoanalysis marks the real beginning of widespread clinical focus on education. Freud's concept that anxiety results in repression and symptom formation and that neuroses were caused by excessive control of impulses led to the idea that psychopathology could be prevented by giving children freedom to develop without the traditional repressive techniques employed both by authoritarian parents and by schools. These ideas coincided with those of John Dewey, who stressed the value of learning through individual experimentation, with limited interference from books or teachers.

Progressive education, predicated on the idea that children, if left free to use their own powers of exploration, would learn about the world through natural curiosity and warm interpersonal relationships, developed from the ideas of Freud and Dewey. Their considerable impact on American education began in the 1930's, but the initial optimism about progressive education waned as it was found that it resulted in no diminution of neurotic disturbance. Apparently innate factors and crucial life situations influence the child's psychic development despite modifications of school attitudes. Extremes of educational practice, either traditional or progressive, are not common today, most educational systems occupying a middle ground.

Following World War II, there was a shift in emphasis from theoretical contributions to educational philosophy to an emphasis on the therapeutic alleviation of the specific educational problems of disturbed children. Along with this change, there was considerable discussion of the prevention of mental illness through the cooperative efforts of clinicians and educators, but the systematic implementation of this concept has been limited.

Role of the Psychiatrist in the School

In the past, psychiatrists functioned largely as theoreticians for experimental educational models and occasionally as consultants, usually for special or private schools. Child psychiatrists, in their practices, have had to deal with school as an important

aspect of the child patient's life. Actually, most referrals of children for psychiatric evaluation originate with school problems. In the past few years, the role of the psychiatrist has expanded in connection with the tendency to develop special classes, with emphasis on community psychiatry, and with increasing acceptance by educators of the value of the psychiatric contribution. A 1963 survey indicated that 174 child psychiatrists work with schools in some capacity. This number has probably increased considerably since, but, as there are over 40 million children in the public schools, the proportion is a very small one.

As a consultant to the school, the psychiatrist acts as a specialist in the understanding of human behavior and its developmental derivatives, both innate and environmental, of motivation, and of interpersonal intervention techniques.

Role in relation to educator. Because clinicians and educators do not share a common frame of reference or language and because status problems arise when one professional enters another's domain, the psychiatrist has many obstacles to overcome in translating his abilities and knowledge into a form useful to the educator. As separately viewed by the psychiatrist and the educator, the understanding of the source of disturbance, methods of intervention, and goals may differ widely. The psychiatrist preparing for school consultation should, therefore, be exposed to educational viewpoints, operational problems, and teaching methodologies; in so doing, he will find himself much more aware of the social forces operating on mental illness and of the extent of clinical and subclinical disturbance in the population.

Consultation. Psychiatric school consultation functions primarily in the areas of consultation to related mental health personnel working in the school (psychologists, social workers, guidance teachers, etc.), consultation to special programs for deviant children, and direct consultation to teachers in class and case management. In the last role, the psychiatrist is in the position of dealing with teacher-class-administration or with teacher-pupil-administration. This has some resemblance to the parent-child-society unit in therapy; but, since there is much less acceptance by educators of this interactional viewpoint, circumspection on the part of the psychiatrist is required. Errors in this area have probably been responsible for most of the difficulties in school consultation.

Teachers come with supposedly external problems—difficult pupils or restrictive administrative regulations—that may actually reflect internalized conflicts about achievement, identification, regression, rebelliousness, etc. The psychiatrist attempts to reduce the defenses of denial, intellectualization, projection, and avoidance and to bring feelings into the open without himself directly introducing the concept of the educator's role in the problem. The con-

sultant conveys his identification with and respect for the teacher's role by relating his own experiences, especially those that counteract his omnipotent image, by demonstrating methods of coping with problems, by communicating general mental health principles, by talking to the teacher as colleague and not as patient, and by recognizing the realistic limitations of both his and the teacher's roles.

Extending role. School consultants usually go through a process of role evolution, in which, after they are considered omnipotent, they are then tested as to whether they can identify with the educator. With successful completion of this phase, the next step is to be helpful on the level of applied psychiatry. Extension of consultative functions into matters of policy setting on an administrative level is the final stage. It is in this last capacity that the most effective preventive mental health measures can be introduced. Pertinent psychodynamic principles can be incorporated into the total educational experience of the child, embracing such areas as teacher-child relations, group and developmental dynamics, school morale, curriculum selection, and teacher training and supervision.

Psychiatric Disorders Related to School

Learning disorders. Learning disabilities are one of the commonest causes for which children in latency and adolescence are referred for psychiatric evaluation and treatment. About 10 per cent of school age children are reported to have learning difficulties of sufficient degree to require special services outside of the regular classroom. Incidence in boys is greater than in girls in a ratio of 8 or 10 to 1. Although there is no absolute correlation between emotional disturbance and learning disorders and although some children with severe pathology learn very well, there is, on the whole, a close relationship between the factors, regardless of the origin of the learning disability.

Etiology. The majority of children suffering from difficulties in learning appear to do so on the basis of a constitutional, neurological deficiency. Maturation lags in the sensorimotor, perceptual, and integrative systems appear to be responsible for difficulties in auditory and visual discrimination, laterality, memory, symbolization, and expressive language. Even in these cases, however, the effects of poor learning experience often lead to emotional disturbance, which complicates the diagnostic and therapeutic procedures.

Aside from those children with a biological basis for disability, there is a group of children with intact neurological equipment who present a picture of psychogenic learning impediment. This group has received considerable attention in psychiatric literature. Although any aspect of learning may be affected by psychological factors, reading disabilities are by

far the most common and most disabling of the learning disorders.

Psychologically, intellectual activity is considered a function of the ego (perception, cognition, integration, reality testing), and inhibition of it represents a restriction of ego function as a result of conflict between impulses and the superego or the outside world. The child's early experiences within the family, especially in the areas of intake of food (which is symbolically equated with intake of knowledge) and curiosity (in efforts to understand birth, growth, death, sex, and bodily functions) influence the child's freedom and interest to learn.

In addition to attitudes toward the intake of knowledge, early attitudes toward the parent affect the learning process. The teacher is identified by the child with the parent, and children learn initially in order to please the teacher and gain his praise and rewards. The teacher-child relationship is, thus, the major tool for learning. Only later, toward adolescence, does the ego-ideal develop and take over as the chief motivator. If the development of relations between parents and child has miscarried in the preschool period, with inadequate resolution of infantile conflicts in aggressive and sexual spheres, the child is not ready to learn within the teacher-child relationship, and learning disorder may result.

Psychogenic learning disabilities. Some examples of psychogenic learning disabilities are the following.

Early negative conditioning. Early unpleasant school situations—such as a harsh teacher; a temporary handicap like undetected poor vision; excessive competition; poor health, leading to excessive absence; being ridiculed; and fear of aggressive peers—can lead to negative associations to school and consequent avoidance of learning.

Oppositionalism. A power struggle with the parents, derived from earlier periods of psychosexual development, may be carried over to the teacher-child relationship, causing the child to use his energies to defeat the teacher and parents in their efforts to make him learn.

Intolerance for anxiety. Children who have been excessively shielded from frustration, challenge, or unpleasant emotions may find intolerable the tension necessitated by initial experiences and expectations outside the home with a strange adult or peer group. They may react with regression or avoidance.

Threat to omnipotence. Children who have developed a defense of omnipotence against perceived threats from the environment have difficulty in putting themselves in the vulnerable position of learner with the teacher and the other children and may react by attempts to divert the class' attention to something in which they excel—often mischief.

Fear of learning. The act of learning may be equated with aggression or sexual curiosity. To look, to see, to know, or to display mastery of knowledge may produce a conflict with the superego or with the

environment relating to earlier unresolved competition with parent or sibling. Fear of retaliation may lead to inhibition of one or several of the ego functions necessary to learning. Carried further, the child may assuage guilt over drives by punishing himself by not learning—for example, by appearing stupid.

Negative symbolic associations to specific learning items. Occasionally, a child forms a unique, personalized association of a negatively charged nature to a minute item or limited area of learning, such as the sexualization of a letter or the castration or deprivation implication of subtraction, which interferes with learning in that circumscribed area.

Deflection of attention by intrapsychic conflict. Some children may be so preoccupied with intrapsychic conflicts on a conscious or unconscious level that the ego is not free to direct enough attention to the learning process to be effective. The ritualistic obsessive-compulsive child is an example of this.

Retardation of secondary process thinking. Since most learning experiences are oriented toward symbolic materials, the child must have the capacity for logical, abstractional, cause and effect, time-sequenced thinking. In psychotic children, primary process thinking may predominate and impair comprehension of symbolic material.

Lack of motivation. Because of special familial circumstances or because of alienation from the cultural mainstream, a child may attach no importance to learning. He is unable to identify with the teacher and derives no satisfaction from mastery of process because the goals of school are meaningless.

Prognosis. Prognosis of the conditions just described varies considerably, depending on the source of the disability, the underlying diagnosis, its severity, and the type and duration of treatment. On the whole, prognosis with emotional disorders of learning is considered more favorable than with those disorders having a neurological basis. Certainly complete restitution of function is possible in the former; in the latter, follow-up studies indicate a persistence of difficulty into adulthood.

Treatment. Therapeutic intervention in emotional disorders of learning must be 2-fold. Where there are continuing blocks to the absorption and integration of knowledge, therapy must be devoted to the amelioration of these blocks. However, children with such disorders are almost always markedly deficient in the necessary skills and requisite knowledge commensurate with their ages, and they will not automatically catch up as a result of treatment. This necessitates the addition of remediation procedures, either concomitant with or following psychotherapy. Although remediation usually requires two professional persons, a therapist and a teacher, efforts to combine this role in the form of therapeutic tutoring have recently been reported. In this process, the learning block and its origin are dealt with simultaneously.

School phobia. "School phobia" is a term used to describe the condition in which a child refuses to attend school because of an irrational fear. The term "phobia" is used in the general meaning of aversion rather than with the implication of the phobic mechanisms of displacement, projection, and externalization, which are not present in all cases.

This syndrome appeared comparatively recently, within the past 3 decades, as a result of compulsory education laws, which made school attendance mandatory up to a certain age, and the syndrome has since been steadily increasing. It accounts for about 2 to 8 per cent of referrals to child guidance clinics. The incidence is about the same for boys as for girls. Occurrence is highest up to the 4th grade, decreasing thereafter. School phobias seem to come from homes in which middle class child-rearing practices are employed.

Diagnostic groupings. The diagnostic groupings underlying the symptom fall into three main categories. Most cases are psychoneuroses, with anxious, obsessional, hysterical, or depressed features. The ego strengths of this group are generally good, as evidenced by adequate or even superior performance in social and intellectual spheres outside the circumscribed symptom.

A second group suffers from personality disorders. They may represent a more insidious, severe, or chronic stage, and they appear more commonly in older children. In these cases, the ability of the ego to integrate the demands of drives, superego, and reality is impaired, and defenses of withdrawal, regression, and projection are present, which result in a constricted personality with little energy beyond that used to cling to the mother.

The third group is a psychotic one, in which the inability to attend school is only one manifestation of the severe underlying illness.

Etiology. School phobia is considered to be rooted in the mother-child relationship. Early dependency ties to the mother have not been resolved because of the mother's need for the attachment. The mother is usually indulgent and devotes herself to gratifying the child's infantile needs, with considerably underlying hostility and guilt. School, the first enforced separation of the symbiotic unit, produces a climate for separation anxiety. The episode is precipitated when imbalance in the mother's emotional equilibrium, due to marital or family-of-origin factors, coincides with an exacerbation of anxiety in the child. Because the child is overvalued at home, school is a challenge to his omnipotence. He may, therefore, be very sensitive to any narcissistic threat. There is often great repressed hostility toward the mother for preventing the child's developing autonomy, and with this symptom the child both satisfies and frustrates the love object. He may also satisfy his need to avoid growing up into a sexual being by remaining a dependent, presexual baby. The father usually plays

a role supporting or enhancing the psychopathology of mother and child.

Clinical features. The typical pattern in school phobia is that of an early latency child who, without apparent reason or as an ostensible consequence of some minor event, expresses great fear of school and wishes to remain at home with his mother. He often has above average intelligence and has previously done well in school. The onset usually follows a weekend or holiday. The child may complain of stomach ache or other pains and may vomit. Bribes, threats, and pressures produce panic and great resistance to returning to school.

School phobia differs from truancy primarily in that anxiety, somatic symptoms, overattachment to family, high valuation of school, and internalized conflicts are present, but acting out and antisocial behavior are absent.

Prognosis. School phobia has been referred to as one of the emergencies of child psychiatry, since the prognosis varies inversely with the length of absence from school. Prolonged absence aggravates the psychodynamic conflicts and adds secondary gains to remaining away from school. The prognosis for return to school is generally good, especially in the psychoneurotic group. Those cases in which there is no return or where absences occur throughout the school career fall into the severe characterological or psychotic group. However, about half of all children continue to manifest subclinical symptoms, such as chronic anxiety and vague somatic complaints, throughout their school careers. The prognosis is less favorable in boys than in girls. This may be due to differences in social expectations of independence directed toward the two sexes, as reflected in a syndrome that is primarily a result of faulty development of autonomy. Prognosis also correlates with the degree of parental pathology.

Treatment. Because school phobia involves child, parent, and school in an interlocking relationship, therapeutic efforts must be directed to all three aspects from the outset. The child should be engineered back to school as quickly as possible, utilizing whatever manipulations of class placement, hours, and the like are necessary. Simultaneously, both parents and child should enter psychotherapy for clarification of the dynamics that have resulted in the pathological interrelationships. The return to school cannot be considered to have any therapeutic significance without resolution of the underlying dynamics, as recurrence of refusal to attend is certain.

Because of the primarily familial origin, family therapy has been used successfully. Attempts have been made to treat school phobia within the school, where therapeutic support for attendance can be provided and where school personnel can aid in therapeutic efforts. It is also possible to administer therapy in the home, where the therapist aids parent and child in the physical return to school. For more severe cases,

hospital therapy, which provides separation from family pathology, is used. Deconditioning of the negative associations to school has also been attempted.

The Culturally Deprived Child in School

Interest has focused recently on a large group of children from the lowest socioeconomic class, who show a disproportionately high incidence of learning disability and behavior disturbance and who have a high rate of school failure. In this group degree of retardation in learning is considerable, and only a small proportion of these children complete high school or enter college as compared with the rest of the population. These children have been referred to as "culturally deprived," "culturally alienated," and socially or culturally "disadvantaged."

Members of this group come from poverty-stricken families alienated from the mainstream of culture who can provide only minimal sustained parental stimulation and opportunities for the children to learn and explore the world. The culturally deprived child enters school with lags in cognitive and verbal skills which incapacitate him from meeting the expectations awaiting him. As a result of this, the child gradually falls behind academically, and behavior problems increase.

Among specific handicaps are (1) limitations in the ability to use abstract symbols, abstract cognitive processes, and complex language for interpretation and communication, with compensatory overemphasis on motoric modes of problem solving; (2) low motivation for academic learning, with inability for sustained application to tasks and goals selected by others; (3) deviance from the perceptual modes commonly employed in schools, such as short auditory attention span and predominance of understanding in spatial rather than in temporal terms; (4) low level of identification with the teacher, whose intellectual pursuits are considered feminine, and, conversely, a high level of identification with peers displaying physical prowess and resistance to authority.

On the other hand, culturally deprived children may possess certain skills and competencies that are superior to those of their middle class peers but that are not fully utilized in school. Among these are accuracy of certain social perceptions, resourcefulness in the pursuit of self-selected goals, sustained involvement in a self-selected task, capacity for independence in self-care, and high capacity for spontaneity of response.

The possibilities for culturally deprived children to obtain optimal benefits from educational experiences without special help are limited. The long range social implications of their school failure are considerable, as it is this group of children who, in mid-adolescence, enter the labor market with insufficient skills for current industrial technology and from which the ranks of the unemployed, the petty criminals, and the drug addicts are formed.

Rehabilitation programs. In an effort to combat the handicaps and utilize the strengths of these children, various special school programs have been instituted throughout the country. These programs have as goals the prevention of initial or continuing failure and the remediation of social, cultural, and academic gaps in the education of the child. Innovations in curriculum have been introduced, with special focus on reading and language, including the use of new teaching techniques and new materials, such as reading primers featuring urban, racially integrated, and realistic characters. Team teaching, which employs specialists in the various curricular areas, and ungraded classes to reduce the onus of retardation are being used. Extracurricular stimulation, such as trips and clubs during and after school and on weekends and vacations, attempt to fill gaps left by the home. Efforts to bring parents closer to the school, to increase guidance programs, to reduce the size of classes, and to recruit better teachers to schools in disadvantaged areas are in operation.

Preventive programs. On the preventive side are the preschool programs. Proceeding on the assumption that the culturally deprived child is, at 5 or 6 years, already handicapped in educational readiness, these programs begin when the child is 3 years old and attempt to provide in school the stimulation heretofore left to the home. All these efforts attempt to bring the lower class child into consonance with the middle class school on the assumption that, despite the continuing differences in lower socioeconomic group concerns and interests, all or most lower class children can enter the middle class through education. Another view would assume that, until the school modifies its goals and concerns to meet the cultural needs of different groups, these children will continue to be at a disadvantage.

Education of Emotionally Disturbed Children

It is estimated that 5 to 10 per cent of school children are sufficiently disturbed to require clinical help. Although private institutions have provided education for disturbed children for a number of decades, special classes for emotionally disturbed children under the auspices of public education are of relatively recent origin. Pressures for these classes came from teachers who were experiencing difficulty in containing and educating certain children and from parents concerned with their children's educational failures or exclusion from school because of emotional illness. Additional influencing factors have been the emphasis on reaching the nonpatient population, such as those who do not seek treatment, and the realization that treatment facilities are too limited and individual treatment too lengthy and costly for the numbers of children requiring it. Psychiatrists and other clinicians have recently shown an interest in education as a treatment of choice as a result of disappointment with the effec-

tiveness of psychotherapy with certain groups of children, such as schizophrenics, and lower class urban children with conduct disturbances.

Along the continuum are programs emphasizing therapy, others emphasizing academic achievement, and still others based on personality or learning theory. Mention may be made of (1) the use of audiovisual or teaching machines to instruct children, usually psychotic, for whom human interaction is anxiety-producing; (2) use of behavioral conditioning with simple immediate reward and punishment systems to induce desired behavior in primitive children; (3) emphasis on sensory, perceptual, or kinesthetic procedures as a basic remediation measure for major learning disorders; and (4) use of curricula designed jointly by clinicians and educators to reduce anxiety, emphasize mastery, support ego functions, and the like.

Special classes, ranging in size from 2 to 15 children, exist within public schools, clinics, hospitals, residential treatment centers, and as separate special schools, the last usually under private auspices. Although many existing classes are a desperate holding action for children excluded from regular classes, some attempt to provide active treatment programs. Programs range along a continuum with regard to theory and methodology.

Therapeutically oriented programs. Therapeutically oriented programs are based on the assumption that a therapeutic milieu or technique is the most effective route to therapeutic and educational goals. Such programs are most often attached to hospitals or clinics, where clinical personnel are available and influential in planning and carrying out the program.

Academic achievement programs. Programs that focus on academic achievement are based on the assumption that maximum exploitation of the educational potential of the disturbed child is the shortest route to his rehabilitation. These facilities are usually designed and implemented by educators. Clinical consultation may be minimal.

Types of disorders. Although the diagnostic range of children requiring special education is wide—covering severe neurosis, chronic brain syndrome, adjustment reactions of childhood, and psychosis—most of these children from the educator's point of view fall into two behavioral categories: (1) the acting out or disturbing child and (2) the fearful, withdrawn, or disturbed child. The former constitutes the majority, with prevalence throughout elementary and secondary schools. Most pressure for special education is, for obvious reasons, for this group of children, but less work on special programming for them has been done. The fearful or withdrawn child, although in the minority and with greatest prevalence in preschool and elementary school, has received more clinical attention, and there has been a greater development of special programs for such children.

Actually, all school behavior disturbances are determined by anxiety, although this may not be externally apparent. The child who acts out instead of internalizing is either showing a symptomatic variation of conflict resolution or, because he comes from a subculture whose standards differ from those of the school, is made anxious by being forced to accommodate to alien standards and thus resorts to the adaptive modes to which he is accustomed. These adaptive modes are intolerable in the usual school setting.

Differences among the types of children who cannot seem to profit from regular classroom experiences are of great significance in educational programming, although overt symptoms may not always give the clue to the differences. For example, a highly anxious, neurotic child with inhibition of aggression may require a flexible approach allowing him the freedom to exercise autonomy and self-assertion. A schizophrenic child, anxious as a result of chaotic boundaries between self and nonself, may require a highly structured classroom milieu to aid in reducing ego disorganization. A child who acts out as an expectation of deprivation may require programming to reduce his constant search for gratification. A child who acts out as an expression of unresolved infantile omnipotence may need the experience of a firm teacher to aid in his adaptation to reality, an experience denied him at home.

The implications of psychodynamic understanding of behavioral symptoms affect not only classroom milieu and teacher attitudes but also educational methodology. Such aspects of programming as timing, routines, level of sensory input, use of materials, and choice of disciplinary measures or such aspects of curriculum as the ratio of fantasy to reality and the relationship of content areas to instinctual drives are influenced by one's understanding of psychodynamics and psychopathology.

Grouping. Because of the wide range of individual differences in children, the problem of grouping is significant. Where selective grouping is possible, homogeneity with regard to required milieu and teaching methodology is, on the whole, preferable. However, this concept must often be modified by peer relationships among the children. A child with a conduct disturbance whose behavior is aggravated by similar classmates may be better able to control impulsive behavior when he is with nonaggressive children. A group of schizophrenic children may become better focused on reality if they are influenced by peers with greater ego strengths.

Evaluation. There is considerable controversy about the trend toward establishing special classes for emotionally disturbed children. The tendency to subdivide children into special groups, according to deviation from the norm, has been marked in recent educational practice, but research evaluations have not, up to now, lent support to the greater value of

special classes in terms of academic achievement, although social adjustment may be improved.

In addition, special classes obscure the concept that some children's deviation may be less symptomatic of psychic distress than of a reaction to the frustrations resulting from conflicting needs of child and school. Clinicians have voiced objection to special classes because they decrease the clinical-educational investment in seeking modes of adaptation and deprive the deviant child of the benefits of normal peer groups. The ecological view of therapeutic intervention—that it is designed not to reconstruct the deviant child but to bring him into balance with his environment—recommends use of special costly resources, such as special classes and hospitalization, minimally, at times of crisis, with the goal of return to the regular facility as quickly as possible.

Long range evaluation of the effects on disturbed children and their peers of education in special versus regular classes is needed.

High School and College Psychiatry

High school and college coincide with the periods of early, middle, and late adolescence, with their physiological, social, and interpersonal stresses. The ego, which works at maintaining psychological homeostasis, is subjected to special stresses in this transitional period, and the results of these stresses are responsible for many of the emotional problems seen in high school and college students. School often becomes the arena to which the many conflicts are brought.

High school. The major psychiatric problems encountered in high schools, in addition to those of adolescence per se, are learning disabilities carried over from elementary school, low motivation, underachievement, behavioral problems, and the phenomenon of the early dropout.

The experience of entering high school, with its increased size, departmentalization, many teachers to relate to, and pressure for achievement, constitutes a stress for the 13- or 14-year old. He may react by loss of impulse control, inability to concentrate, and somatization—all resulting in underachievement and its secondary disadvantages. The adolescent with delinquent trends is resistant, hostile, and suspicious of school; it is here that the greatest conformity to authority and control is expected of him. His failures will be exposed to his peers, before whom he must maintain a strong facade. His adolescent narcissism is threatened by failure, and he avoids the danger by the acting out of rebelliousness. Since high school attendance is mandatory in this country and there are few alternatives available for the adolescent who is poorly equipped or motivated for it, the high schools and a good proportion of their students are deadlocked in a struggle in which there are few avenues for resolution.

Therapeutic programs. Therapeutic and other in-

intervention programs to aid in these problems include individual and group counseling and therapy, modifications in curriculum in the direction of greater activity and practicality and less formality, work-study programs, vocational training, smaller classes, remedial programs, and extracurricular enrichment. Results have been equivocal. Since there is a high correlation between family pathology and cultural deprivation and high school difficulties, preventive efforts in earlier years may be more effective. There is also room for experimental programs, particularly those based on the concept of practical alternatives to mandatory high school attendance.

College. There has been a steady increase in the number and size of college psychiatric services offered in the last 2 decades. Many institutions offer comprehensive diagnostic, counseling, and psychotherapy services. Where such services exist, they are used by about 10 per cent of the student body.

The 17- or 18-year-olds entering college are a selected group. They have performed well in previous schools, have higher than average intelligence, are highly motivated, and come from families with a high investment in them. Despite all this, insecurities abound. This is a period of transition to adulthood. For many it represents the first complete separation from home, with its consequent exposure to different standards and values and increased autonomy, responsibility, and freedom. The need to succeed competitively in academic, social, sexual, and possibly athletic spheres is very great. Problems in the areas of dependency, sexuality, self-esteem, and achievement of identity require resolution.

Etiology. Emotional problems in college students correlate highly with disturbed home environments. Divorce, discord, and mental illness are common. Family attitudes of inconsistent discipline, inadequate role differentiation, rigidity, overly high or unreal expectations, and unfavorable comparison of the child with other siblings seem to play a causative role in the student's adaptive breakdown in college.

Diagnosis. Depression, early schizophrenia, and all forms of neurosis and personality disorders with impulsive behavior predominate. Conflicts are expressed not only as psychic symptoms, especially anxiety and depression, but in the form of poor grades, inability to concentrate, somatization, overactivity, antisocial behavior, and a variety of sexual behaviors, including compulsive sexuality, homosexuality, and illegitimate pregnancy. Minority students attempting to achieve social mobility in college, students supporting themselves, students under pressure to achieve high grades, students from highly protected environments, and students moving from rural areas to cosmopolitan centers are all high risk groups. There is a seasonal incidence of difficulties at examination times, when the defenses of avoidance, evasion, rationalization, and projection break down. One of the greatest problems is the high drop-

out rate; 35 to 40 per cent of students do not graduate. This cannot be explained on the basis of lack of intellectual capacity, as there is no significant difference in I.Q. or extent of academic difficulty between those who remain and those who leave.

Treatment. Brief psychotherapy is very common in college services, partly because of policy and scarcity of staff but also because students are particularly suited to this form of therapy. They tend to make rapid emotional contact, are labile, act out transference feelings and unconscious conflicts, and exhibit a wide range of regressive and progressive swings. Their youth, physical attractiveness, intelligence, and verbal ability are also therapeutic assets but are risks for counter-transference phenomena, such as overidentification and overprotectiveness. Counseling programs, using faculty members as advisers in educational matters, are in wide use. Ideally, these should be integrated with psychiatric services, with the counselor handling minor emotional problems with consultation and referring more serious ones to the mental health service.

The practice of psychiatry within an institution dedicated to higher education is considerably influenced by the attitude of the administration and the faculty toward it. Colleges have traditionally espoused a policy of survival of the fittest, not of those less fit. The emphasis on the part of the college community on intellectualism, scientific objectivity, and the accumulation of knowledge is subtly opposed to the emphasis by the psychiatrist on affectivity, interpersonal relationships, and the importance of the unconscious. In practice, the college psychiatrist is often confronted with conflicts between students and administration in which his dual role as physician and college official requires delicate balancing. In order to function with any effectiveness, the practice of psychiatry at any college must have sanction and approval on the highest administrative level.

43.7 PSYCHIATRIC TREATMENT OF ADOLESCENTS

JAMES F. MASTERSON, JR., M.D.

This section describes some special characteristics of the initial phase of the therapeutic encounter with adolescents.

The Participants

The adolescent does not have the final decision about treatment and may feel disillusioned with and suspicious of all adults. The parents, on the other hand, do have the final decision and are often burdened with both guilt and anger. Furthermore, the adolescent is usually in a state of regression when first seen, and he usually expresses his emotions indirectly, through his behavior, rather than verbally. In addition, he has certain emotional needs that have to be met in treatment.

The most useful qualities in the therapist who treats adolescents are directness and flexibility—a willingness and ability to handle issues directly as they arise, a capacity to follow the trends in the patient's behavior without dogmatic theoretic bias, and an ability to alternate his therapeutic role quickly as the situation demands.

Consultation

Treatment can be viewed as a continuous process from the initial consultation until the termination of psychotherapy. With the first phone call, the therapeutic process begins as the therapist gathers information on the problem, formulates his approach, senses the focus of the parents' anxiety, and often advises them how to explain the consultation to the adoles-

cent, thereby minimizing such difficulties as the adolescent's regarding the consultation as punishment or an effort to force him to conform. The independence of the adolescent is indicated immediately by seeing him first, requesting his permission to see the parents, and stressing the confidential nature of the contract.

Unlike therapy with adults, therapy with adolescents places the burden of contact on the therapist; therefore, he must attempt as soon as possible to get an adequate appraisal not only of the patient's problems but also of anticipated transference reactions and resistances. Interviews with parents often help the therapist to this goal by providing evidence of their unconscious attitudes toward the patient. These attitudes will form the basis for later transference manifestations. Projective tests, such as the Rorschach, are also helpful.

Since the adolescent does not have final control and since the parents are often embroiled with anger, guilt, and denial, the therapist truly carries a parent-like responsibility. He must decide what treatment is necessary, whether or not the parents can afford it, and whether or not he is the appropriate person to conduct it. Few therapists can treat all adolescents. The way in which the therapist resolved his own developmental problems often makes him suited to one adolescent and unable to treat another. He then must formulate the situation in such a way as to maximize motivation for treatment. In order to deal with the parents' resistance, it may be necessary to emphasize the gloomy outlook if the adolescent does not receive treatment.

The parents' guilt about their role in the patient's problems should not be assuaged but should be used to motivate them to seek help. Conjoint treatment of the parents by a social worker gives added emphasis to the therapeutic impact, especially if the social worker is supervised by the psychiatrist treating the adolescent. The need to involve the parents varies with the developmental stage of the adolescent; the closer to early adolescence he is, the more necessary it is to involve the parents; the closer to late adolescence he is, the less necessary is parental involvement.

Initial Phase

If the consultation has been handled properly, the stage has been well prepared for treatment. It should be quite clearly implied to both parents and adolescent that the goals of treatment are the independence, health, and reality orientation of the adolescent. This is of great help in handling therapeutic issues when they arise later.

With the formal beginning of therapy, the therapist attempts to establish a therapeutic contact and contract by first understanding the patient's initial defensive maneuvers. Then he interprets these maneuvers in terms of their current interpersonal un-

conscious meaning rather than their historical context. More simply, the therapist attempts to understand the emotional message the patient is trying to convey by his behavior; then he reads it back to him. This technique establishes the therapist's interest and competence and tends to overcome the adolescent's suspiciousness and testing. The cornerstone of all therapy with adolescents is telling them what they feel, rather than expecting them to tell you, and then responding appropriately to the indicated therapeutic needs. Since the messages expressed are as varied as the number of patients one sees, the therapeutic responses also vary and include interpretation of the unconscious, direction, support, limit setting, interference with parents' destructive behavior, and interested silence. A case described below illustrates one response.

Dave, a 17-year-old boy, the third of three children, had a 3-year history of depression, culminating in a serious suicide attempt. He suffered from a severe character disorder of the deprived affect type, which was masked by a rigid obsessive-compulsive facade.

The patient's past history was that of a compliant, eager to please, subservient child; he was able to adjust fairly well throughout childhood until onset of adolescence, when his submissive relationship with his brother raised unconscious homosexual conflicts. He became depressed, left home for prep school in search of relief, went on to college, and finally made a suicidal attempt after a series of interviews with a psychiatrist.

Underneath his compulsive facade, the patient felt (1) utter futility at the possibility of anyone caring for him, (2) sadistic and masochistic fantasies and impulses, (3) homosexual impulses, and (4) great anxiety about control. Interviews with the parents revealed that, despite their verbal protestations to the contrary, they had little interest in or responsiveness to Dave. The father, constantly out of the home, atoned for his guilt by overindulging the patient materially and never attempting to set limits for him. The mother used the patient for emotional support and infantilized him.

In the interview with the patient, he presented a bizarre and rigid smiling face, which masked his underlying depression. He showed contempt for the father, doctor, and all authority figures, and he caricatured psychiatry. In addition, he gave a history of "putting people on," putting up a facade to see if they would discover his feelings behind it. He also hinted at several abortive and dismally unsuccessful attempts at heterosexual intercourse.

The consultation interviews suggested that the patient's initial transference reaction would be a feeling that the doctor, like all authority figures, was incompetent, was not deserving of respect or trust, and did not care about him. Therefore the therapist should deal with the patient's initial testing maneuvers by (1) confronting the patient with the feelings beneath his facade, (2) setting limits to help give the patient control, and (3) providing him with alternate ways of dealing with these feelings.

The therapy began with the patient's joking about the fact that he expected no help from anyone, didn't care about himself, planned more suicidal attempts but "was giving the therapist a chance." The therapist responded that the patient was trying to put him in a bind so that, if things did not go well, the therapist would be responsible for a suicidal attempt. The doctor then stressed that he could not accept this bargain—that, though the patient needed help, the therapist could not do the job alone; he required the patient's cooperation. The therapist then said that, if the patient wanted to commit sui-

cide, he would not be able to stop him but that this was a mis-carried effort to deal with his problems. Next, the therapist interpreted the patient's joking behavior as an effort to "put the therapist on." He pointed out that the patient had a long history of similar efforts with all people, efforts that were followed by a feeling of delight when the people were able to perceive his underlying feelings. Then the therapist noted that the patient's family was not interested enough to try to penetrate this facade.

When the therapist scheduled him for an early morning hour, the patient joked at great length about getting up early. The therapist brushed this aside with a simple comment that the patient was angry. The patient revealed that he had fantasies of throwing bricks through windows and of punching people in the nose. The therapist then tried to indicate alternate ways of handling these feelings by saying that, rather than smiling and making a joke about it, the patient should verbalize his anger.

During a reluctant but frank admission of sexual difficulties, the patient dramatized his regressive behavior by eating lollipops, playing with children's toys, refusing to get a job. The therapist, feeling that the relationship could sustain the challenge, told the patient directly that the regressive activity was a running away from his problem, probably because he felt he couldn't handle it; that he wanted to be a child to escape his sexual feelings, and yet he also wanted help; that he was working at cross purposes with himself, since it is not possible to have both—either he had to involve himself and use the help offered to deal with and master his problems, or there was truly little hope.

This example shows how the therapist, basing his approach on the dynamic constellation revealed in the consultation, actively attempts to establish a relationship by clarifying the current interpersonal unconscious meaning of the patient's testing behavior and then responding appropriately to the indicated therapeutic needs.

Chapter 44

Special Areas of Interest in Child Psychiatry

44.1 MATERNAL DEPRIVATION

LEON J. YARROW, PH.D.

Maternal deprivation is one facet of the much larger issue of the role of early maternal care in personality development. Although the importance of mothering experiences in infancy and early childhood has long been recognized, it is only in the past quarter of a century that research evidence has begun to document the effects on the development of young children of a variety of inadequacies and deviations in maternal care. A comprehensive review of the research and clinical literature was prepared under the auspices of the World Health Organization in 1951 by Bowlby. On the basis of this review, Bowlby concluded that a warm, continuous relationship with a mother figure is essential for healthy personality development. This monograph activated the dormant concerns of clinicians working with children and also stimulated loose generalizations about the deleterious effects of any form of deviation from Western middle class patterns of maternal care. Subsequent reviews of the literature have tried to sort out the varied kinds of discontinuities, inadequacies, and distortions in maternal care that have been included under the rubric of maternal deprivation. These reassessments have pointed out the methodological deficiencies of some of the earlier investigations and some of the conceptual flaws underlying the interpretations of the data from these studies. These evaluations and the subsequent more focused research have not negated the basic conclusions of the earlier studies but have refined and extended them.

Deviations in Maternal Care

Four major kinds of experiences with potentially different implications for personality development can be distinguished in the research literature (Yarrow, 1961): institutionalization, multiple mothering, separation from a mother figure, and distortions in the affectional relationship between mother and child.

Institutionalization. The greatest share of data has come from studies of infants and young children who have experienced institutional care at some point in their histories. Conclusions about the effects of institutional care come from two major sources: direct studies of infants and young children living in institutional environments and retrospective studies of older children and adults with personality disturbances.

There is consistency in the general findings that infants subjected to prolonged residence in very poor institutional environments develop intellectual and personality deficiencies and disturbances. Not all aspects of development are equally affected by early environmental deprivation. Early motor functions that seem to be most dependent on maturation seem to be least affected; perceptual-cognitive and language functions seem to be most vulnerable. Evidence of intellectual and language retardation appear very early in infancy and become intensified with continued institutionalization. Perhaps the most serious effects attributed to institutional care are personality and character disorders. Infants growing up in institutions often fail to develop normal patterns of social responsiveness; they tend to become withdrawn and apathetic, and frequently they do not develop normal patterns of social discrimination. These early deviations in personal-social behavior are considered precursors of personality deviations in adolescents and adults characterized by poor impulse control, lack of appropriate guilt feelings associated with aggressive and destructive behavior, and an inability to establish close and meaningful interpersonal relationships.

Although the early literature suggested that severe intellectual retardation and personality disturbances were inevitable outcomes of early institutional care, recent research has found considerable variability in the level of retardation and degree of disturbance in children in different institutional settings. Moreover, similar personality and intellectual dysfunctions are often found in children who have been exposed to environmental deprivations and distortions in maternal care in their own homes. These findings lead one to question whether all the deviations in intellectual and personality functioning found in institutionalized

children can be attributed simply to one variable—the lack of emotional interchange with a single mother figure. It seems likely that the absence of the mother figure is associated with a number of other more direct variables operating in institutional and other environmental settings.

In recent years, studies have begun to analyze more precisely the dimensions of institutional environments. This research suggests that such variables as the following need to be considered in analyzing the impact of institutional care: the amount, the quality, and the variety of sensory and perceptual stimulation provided directly or mediated by the care-taker; the extent of opportunities for acquiring and practicing skills; the timing and appropriateness of the care-taker's responses to infant's behavior; the degree of continuity of care provided by a single mother figure; the quality of affectional interchange with substitute mothers. There appears to be a direct relationship between the extent of intellectual and language retardation and the degree of sensory and verbal stimulation in the institutional environment. Studies of extremely poor institutions on the one hand and studies of institutions that have attempted to provide individualized care and adequate stimulation on the other hand further corroborate the importance of these variables. Other studies have begun to identify some of the other factors that modify the effects of these environmental variables, such as the age of the child at the time of institutionalization and the duration of institutional care.

One aspect of the institutional environment that has been implicated in the development of deviant social responsiveness and later problems in interpersonal relationships is the lack of continuity in the mother figure. The multiplicity of care-takers tends to create an unpredictable environment for the young child; he has limited opportunity to develop consistent expectations toward one person. Moreover, care-takers are unlikely to individualize children and to adapt their handling to the child's unique characteristics, thus limiting the kinds of reciprocal interactions that are basic to the development of meaningful interpersonal relationships and normal patterns of identification.

Findings on the direct effects of impoverished environments on infants and young children are more clear cut than are the findings on the long term effects. Studies of long term effects tend to be limited because of a number of methodological inadequacies, the most important being the lack of control groups and unreliability of retrospective data. Several recent and more carefully controlled retrospective studies have begun to raise questions about the conclusions of the earlier retrospective studies. In studies by Howells and Layng and by Schofield and Balian, control subjects without any apparent symptoms reported early histories as pathogenic as those of the subjects with overt personality disturbances. Other in-

vestigators, such as Beres and Obers, Gregory, and Pringle and Bossio, present evidence that long term outcomes may depend on the character of the earlier experience, the age at which it occurred, and subsequent experiences in maternal care.

Multiple mothering. Although there is some evidence of the harmful effects of multiple mothering in institutions, multiple mothering is not always associated with severe deprivations or traumatic discontinuities in care. The presence of more than one mother figure may be associated with more varied stimulation in the context of individualized care. Studies of children in the Israeli kibbutzim, in university home management houses, and in other cultures suggest that being cared for by more than one mother figure may not be inherently detrimental to young children. Margaret Mead has suggested that children who are reared in cultures in which the child care functions are shared by a number of mother figures are better equipped to tolerate separation and often develop more subtle and more complex personality characteristics, presumably as a consequence of having more varied identification figures than children in cultures where a single mother figure is the rule. It seems clear that the effects of multiple mothering depend on the specific patterns of interaction between child and mother and on the larger social context.

Maternal separation. Maternal separation and maternal deprivation have often been used interchangeably. Although maternal separation frequently precedes deprivation of maternal care, deprivation experiences are not a necessary or inevitable aftermath of separation. It is important to distinguish between the effects of a break in the continuity of relationship with a mother figure and the effects of stimulus deprivation.

Maternal separation occurs under a wide range of circumstances, such as temporary separations involving operative procedures or short term hospitalization of the child for acute illness; hospitalization of long duration for chronic illness; temporary separations due to illness of the mother; permanent separations from parents due to death, desertion, incompetence, or cruelty of a parent; single temporary separations followed by the provision of a permanent substitute parental figure, as in adoption; recurrent separations from natural parents followed by institutionalization or foster home placement; recurrent separations from foster parents. The psychological significance for the young child of each of these different types of experiences is likely to be very different.

A break in the continuity of relationship with a mother figure is a disturbing experience for infants and young children, as evidenced by their behavior at the time and immediately following separation. The long term effects of separation experiences during infancy and early childhood are less clear cut. Several studies find a characteristic sequence of responses to

separation in hospitalized or institutionalized children. At first, separated infants tend to show overt protest and active seeking of human contact in an apparent attempt to find a substitute mother. This behavior is usually followed by active rejection of people. Finally, the child withdraws from his environment and shows depressed behavior. Bowlby has pointed to the overt as well as dynamic similarities between withdrawn, depressed behavior in infants and young children and mourning in adults. The progressively severe depressive reactions occur in children who are placed in impersonal environments without adequate substitute maternal care. Infants who are given individualized substitute maternal care may show similar initial disturbances, but the progression in severity of symptoms is not likely to occur.

As with sensory deprivation, the meaning of separation depends on the developmental level of the child. It is clearly very different for the 2-month old infant than for the 8-month old who is at the height of stranger anxiety. For the very young infant, separation may be perceived simply as a global environmental change. He may be aware of a changed physical environment—of changes in timing of daily events and in experiences of sleeping and feeding, in the speed with which his needs are gratified, and in the modes in which gratifications are provided. It is not until the infant has developed a focused relationship with a mother figure that the loss of a specific person becomes important. The period between 6 months and 2 years appears to be an especially vulnerable one.

There are no clear data on the extent to which the degree of disturbance at the time of separation is prognostic of the severity of later effects. The findings on the long term effects of early separation experiences are more equivocal than the data on the immediate effects. The implications of separation experiences for later personality development depend on a number of factors: whether the separation is temporary or permanent, the duration of a temporary separation, the total context of the child's life experiences, the number and character of previous separation experiences, the age of the child at the time of separation.

Perhaps most significant with regard to the long term consequences is the degree of trauma or deprivation subsequent to separation. It appears that brief, temporary separation experiences are not likely to have serious permanent effects, but serious personality disturbances may develop in children who have been subjected to repetitive separations associated with other traumatic and depriving experiences during infancy and early childhood. If temporary separations for medical care are handled skillfully to maximize the continuity in relationship with the parents and to minimize associated traumatic experiences, permanent damage is unlikely.

Pathological mother-child relationships. Fre-

quently included in the concept of maternal deprivation are the deviations in the mother-child relationship characterized by rejection, hostility, and ambivalence on the part of the mother—disturbances that are often rooted in personality or character disorders in the mother. Unlike the experiential deprivations attendant on lack of sufficient interaction with a mother figure or discontinuities in the maternal relationship, these deviations are primarily in the *quality* of the affectional relationship. The extensive clinical literature on this kind of deviating maternal relationship suggests effects (e.g., schizophrenic, depressive, and neurotic disturbances) which are different from those associated with deprivation, separation, or multiple mothering. The effects of severe disturbances in mother-child interaction are best understood if they are seen on a continuum with a wide range of attitudinal and personality characteristics of the mother and child-rearing patterns.

Variables in Maternal Deprivation

The literature emphasizes the complexity of the concept of maternal deprivation. A great variety of events and environmental circumstances precede, occur concomitantly with, and follow the separation of a child from his mother. For greater theoretical understanding as well as for more effective planning of therapeutic and preventive programs, it is useful to analyze specific variables rather than to attempt to deal with an undifferentiated global entity.

Recent human and animal studies have helped to define more precisely the significant components of the early environment and to identify some of the variables that interact with and modify early experiences. These investigations offer new theoretical perspectives for understanding the underlying mechanisms of early environmental influences. The major theoretical issues emphasized in these studies are: the importance of appropriate sensory and perceptual stimulation during infancy and early childhood; the concept of environmental contingencies in learning theory, pointing up the importance of the conditions under which stimulation is provided; the critical period hypothesis, which emphasizes the importance of the timing of experiences, that is, the point in the developmental cycle at which a specific kind of experience, trauma, or deprivation occurs; the increased understanding of constitutional differences and the accompanying emphasis on the selective responsiveness of the young organism to his environment; and finally the shift in emphasis from early environmental determinism to an awareness of the role of subsequent life experiences in reinforcing or ameliorating the effects of an earlier depriving or stressful experience.

Sensory deprivation. An important aspect of early maternal deprivation is sensory deprivation. The mother in the course of normal maternal activities serves both as a source of stimulation and as a medium for bringing the infant into contact with

appropriate environmental stimuli, sometimes enhancing and sometimes buffering the intensity of stimulation. The importance of sensory and perceptual stimulation in early development is well documented by a large body of experimental studies with animals. These studies indicate that severe sensory and perceptual deprivation in early life may adversely affect the development of the sensory processes and the basic underlying structures in the central nervous system. Hebb has emphasized the importance of early stimulation, postulating that early experience may influence later behavior by structuring the organism's perceptual capacities. Hunt, elaborating on Hebb's thesis, stated that "the intrinsic regions of the cerebrum must be properly programmed by preverbal experience if the mammalian organism is later to function effectively as a problem-solver."

Stage of development. There are conflicting opinions as to how early sensory deprivation, stress, or trauma begins to have an effect. A number of studies suggest that the younger the organism, the more vulnerable it is to adverse environmental impacts. A growing body of data, however, points to the importance of the developmental stage at which such experiences occur. The basic thesis of the critical period hypothesis is that sensitivity to given kinds of stimulation and vulnerability to specific types of deprivation or stress vary at different developmental periods.

In the studies of stimulus deprivation, there has not yet been much consideration given to the modalities of stimulation. Some data hint at differential effects of deprivation in given modalities at different developmental periods. For example, Harlow's research on infant monkeys suggests that tactile stimulation is of greatest importance during the earliest period of development but becomes less important later in infancy. We do not know whether one can generalize across species with regard to the relative sensitivity of given sensory modalities at different developmental points. With regard to separation experiences, it seems very clear that sensitivity to maternal separation is highly phase-specific. The effect on the young infant of giving up a mother figure before a strong dependency relationship has been developed is very different from the experience of separation during the period when a relationship with the mother is developing and after a focused relationship has been established. Similarly, the young child's reaction to the loss of a mother figure at later developmental periods may vary with the degree of autonomy he has achieved.

Individual differences. In addition to sensitivities and vulnerabilities characteristic of specific developmental periods, a growing body of evidence suggests the importance of basic individual differences in determining the impact of early experiences. There may be individual differences in general susceptibility to stress as well as differences in sensitivity to particular

kinds of stimulation. Recent studies have emphasized the extent to which the infant influences the kind of stimulation he receives and particularly how infant characteristics influence maternal behavior. With the development of techniques for measuring basic differences in autonomic functions and in physiological-behavioral responses, one can anticipate rapid progress in understanding the interaction of constitutional factors and early environmental influences.

Prognosis

Research is sparse with regard to the reversibility of the effects of early sensory deprivation and early separation, and the findings are equivocal. Data suggesting permanent damage have almost without exception been based on studies of subjects who have experienced recurrent severe deprivation or trauma throughout infancy, childhood, and often through adolescence. On the other hand, a number of follow-up studies find no severe impairments in adults who had been separated from their mothers in infancy and placed in various kinds of group settings preceding adoption. The interpretations of these findings, however, depend on the level at which the individual's functioning is assessed. Several investigators have speculated that, although these subjects were apparently making adequate adjustments, a deeper level of analysis might reveal psychic scars or distortions in psychic functioning that manifest themselves only under conditions of stress.

Maternal deprivation is not a simple etiological entity, and one can no longer make any easy generalizations about its effects. There is no given set of experiences or standard pattern of maternal care that insures healthy personality development or that leads inevitably to retardation and personality distortion. The new research and theoretical perspectives emphasize the complexity of the interrelationships among organismic variables, immediate environmental factors, and the total experiential context.

Suggested Cross References

Current concepts of the genesis of all the functional psychoses, psychoneuroses, and personality disorders involve hypotheses concerning disturbances and deprivations in the patients' early mother-child relationship. The reader is referred to Area F, on the psychiatric syndromes, and to Chapters 41 and 42 for detailed discussions of specific disorders.

44.2 TWINS

PETER B. NEUBAUER, M.D.

Twinship has received particular attention, for it has to do with a unique psychological experience and, in the case of monozygosity, a unique constitutional condition. Approximately 1 in 86 births is a birth of twins; between a third and a fourth of the total twin population are monozygotic.

Development

Early development. The development of twins is characterized by a number of special factors. The somewhat lower performance of twins, as compared with other children, may rest on the fact that very often—60 per cent of births—twins are born prematurely and may, therefore, have a biological handicap. They also have psychological variables. Personality differences in twins appear during the first years of life and are usually based on which of the pair is active and which is passive at a given time. Since the two children appear to function as a unit, one can observe a division of roles between them: when one twin is more active and dominant and initiates behavior, the other takes the more passive role. Thus, the active twin could develop more fully the traits of aggressivity and self-reliance, and the other would tend to become altruistic, submissive, and dependent. These features seem at first to be determined by physical differences at birth as to which twin is the stronger and better developed at that time. But as the other child becomes able to bridge this gap or to enjoy certain other advantages, these roles may be reversed.

Twinning. These early differences, which one would assume to lay the groundwork for the twins' divergent personality development, are modified by an important factor, which becomes operative as the twins grow older. Around the age of 3 or 4, the processes of identification and imitation and their reactions to their mirror images limit the significance of the earlier differences. One twin learns to enjoy the other's activities and to feel the punishment the other receives. This interaction, called "twinning," is

a most important influence on their further development. At this time, the twins begin to move away from the mother and to establish an independent interplay with each other. This mutual interdependence may result in a lack of individuation. Their emotional and physical proximity to each other at each phase of development throughout childhood makes the twin relationship different from that between siblings. This mutual interidentification and increasing interdependence may provide certain handicaps for twins, leading not only to difficulties in achieving individuation but also to limitations on their capacity for conceptualization and learning. Findings indicate that twins' intelligence measures are inferior to the levels of matched groups of nontwins. There is also a lag of linguistic development, which seems to be correlated with their difficulty in establishing a mental image of their own bodies (identity), as seen in the delay of the distinction between self and mirror image and the delay in use of the pronouns "I" and "me."

Mothers' reactions. Mothers seem to have a natural feeling of pleasure when they are first told that they may expect twins. After the birth, however, they may encounter unanticipated difficulties, which arise from the necessity of having to adopt at the same time a mode of interaction with two children with different characteristics. Some mothers even stress these differences in order to learn how to perform their task and to find the range of their own individual reactivity and sensitivity to their children. Others attempt to resolve the problem by treating the two children as one; they thereby feed into the problem of twinning. Thus, the mother, too, has to cope with the problem of similarity and dissimilarity, individuation or sameness. If the twins are to reach their own individual capacity, her attitude is decisive. Later, the tendency of the twins toward closeness to each other may give the mother the feeling of being excluded. If she enjoys the fact that the children demand less of her personal attention, she may foster the twinning reaction; if she resists their exclusion of her, she may find that twins are an exceptional burden. When the differences between the twins are overstressed, thus forcing a polarity of personality characteristics, there is, again, a retardation of individuation and an interference with full development. Thus, it is difficult for the mother to judge where the balance properly falls between concordance and discordance of interests and traits.

Sex. The sex of the twins and whether or not they are of the same sex has to be taken into account, as well as the environmental influences that may either assist or retard individuation. The situation is easier with fraternal twins. Psychological scales have revealed that opposite-sexed fraternal twins range in an intermediate position between identical twins and same-sexed fraternal twins. This may be related to the fact that girls tend to be the dominant part-

ners in the twin couple during childhood, reversing the indices of femininity and masculinity. Other findings show that twins, especially identical twins, marry less often than controls; and in one study 70 per cent of identical twins at 17 to 20 years of age still slept in the same bed. However, the assumption on the part of individual case studies that there may be a greater tendency toward homosexuality among twins is, as yet, not sufficiently substantiated.

Recommendations to assist development. Twins should not be treated as one; they should always be dealt with in terms of their separate individuality. Differences in their tastes, their rhythms, and their perceptions should be recognized and maintained. One should not praise, reward, or punish both twins as a unit. A most important contribution can be made in this respect by the school. If the twins are placed in separate classes, they can receive independent attention and thereby gain in individuation. One should not interfere with their natural closeness by separating them forcefully or too early. One should stress those characteristics that differentiate one twin from the other, characteristics that correspond to the natural talents and interests of each. The fact that most twins have each other to play with should not delay entering them into nursery school, where they will have the opportunity for exposure to other children of the same age.

Research on Twins

Twin research has received major attention, since it provides a unique opportunity to study the experiential factors of behavior and to delineate constitutional influences. The controversy between heredity and environment must be taken outside of an either/or proposition; it must be accepted that environmental variables can change the morphological and functional characteristics of the organism. Still, interest in the constitutional aspect of many of the psychiatric disorders has been most successfully explored through the study of monozygotic twins.

One of the great problems in twin research is the question of twinning, since this constitutes a unique environmental influence that in itself brings about a variance between the development of twins and that of other children. In order to exclude twinning as a factor, it is necessary to study monozygotic twins that have been separated from birth. Many investigations have been made into the development of twins who have been separated during their lifetime; very few can be found in which the separation occurred at birth.

44.3 CHILDREN'S DREAMS

PETER B. NEUBAUER, M.D.

The dream has been termed the royal road to the understanding of unconscious processes. It permits the study of psychic mechanisms and the examination of the wishes, fears, and conflicts that are unknown to the conscious mind. In modern times, particularly since Freud, there is more knowledge about the psychological content of dreams than formerly, but the physiological aspects of dreaming are just beginning to be understood.

Content of Dreams

Dreams in a child are quite important, since they can have such a profound effect on the child's behavior. During the child's first years, when the differentiation between reality and fantasy, between wish and fact, has not yet been fully achieved, the dream may be experienced by the child as if it were true or could be true; thus, the child has strong reactions to it, either of pleasure or, as is most often reported, of fears.

The dream content is to be seen in connection with the life experience of the child, his developmental stage, and the mechanisms specifically employed during dreaming. There is also a difference in the content of the dreams of boys and girls. However distorted the content of the dream may be, it is generally considered to be a reflection of life experiences, which continue to call for mental activity during sleep. In order to help the child, the therapist must find the relationship between his dreams and the realities of life.

Dream interpretation today is an important part of the armamentarium of psychotherapy. It has not diminished in importance during the last few decades at the hands of those who have learned how to use it. The significant approach is not so much toward the

understanding of symbolic meanings as it is toward the uncovering of those life experiences that contribute to the disorder. Primarily, it is to assist in the reconstruction of events and in the exposure of nonconscious wishes and aggression that are part of the pathology.

According to his psychic organization or his level of development, the child will react differently in his dreams to external situations; the changing content of the dream through childhood provides evidence for this. Some studies indicate that disturbing dreams reach a peak when the child is 3 years, 6 years, and 10 years old. At the age of 2, the child may dream about being bitten or chased; at the age of 4, there are many animal dreams, and people are introduced who can be either good or bad, who either protect or destroy. At 5 or 6, dreams of getting killed or injured, of flying and being in cars, and of ghosts become more prominent, exposing the role of conscience, of moral values, and of increasing conflicts around these themes. The earlier assumption, therefore, that the dreams of very young children are primarily of a wish-fulfilling nature, does not appear to be borne out. It is interesting to note that in early childhood aggressive dreams seem to occur rarely; instead, it is the dreamer who is in danger, which may reflect the child's dependent position.

Dreams and Sleep

Dreams and sleep are so interconnected that it is not possible to speak about one without referring to the other. Freud's original proposition that the dream is the protector of sleep has evoked new interest as the result of recent physiological experiments. The dream, which is a normal and essential psychophysiological phenomenon, may at times interfere with sleep.

At certain periods, a child wakes up from his sleep, disturbed by the content of his dream and extremely frightened; he is unwilling to return to sleep unless he is comforted. Pavor nocturnus is a severe state of fright in which the content of the dream overwhelms reality, so that the child remains frightened by the dream for an extended period of time. During night-terrors, the child remains in this "in-between" state, from which he cannot be fully aroused and restored to reality. The people around him either are not recognized or else are of minor significance as compared with the impact the dream still has on him. The dream seems to continue, even though the child's eyes are open. The child incorporates some pieces of his actual environment into the dream, or else he projects the dream into his environment.

Between the ages of 3 and 6, it is normal for children to want to keep their door open or a light burning so that they can maintain contact with their parents or view their room as they know it to be and not as they fear it to be. At times, they resist going to sleep in order to avoid the dream experience.

Disorders associated with falling asleep are, therefore, often connected with the dream experience. Rituals are set up as protective devices designed to make safer the withdrawal from the world of reality into the world of sleep.

When sleep disorders occur as the result of frightening dreams, it is important to open up the possibilities for helping the child cope with those experiences that seem to overwhelm him, by directing his inner needs into appropriate channels. Symptomatic help, such as sedation, may be useful to only a limited extent. It is generally agreed that, when a child comes into the parental bedroom to seek protection, he should be taken back into his own room and calmed while he is in his own bed so that the original sleeping arrangements may be maintained.

Since sleep disorders seem to be on the increase, more attention will have to be paid in the future to the relationship between dream and sleep, particularly in early childhood. Somnambulism is frequent; very often the content of the dream seems to release motor discharge, and the child tries to go to those persons and places that can offer him protection. There is an assumption that all those impulses not acted on during the day are acted on during the night, and studies have been undertaken to investigate this "balance"—as if those children who are more active during the day and who gratify their wishes and aggression are less subject to disturbing dreams. Pavor nocturnus sometimes occurs after puberty, and nightmares occur during both puberty and adolescence.

Diagnostic Use of Dreams

Many clinicians consider the dream to be an important source of information for the assessment of internal conflicts, for clues concerning the actual life situation, and for determination of the age-appropriateness of the child's development. Dreams are, therefore, used like projective tests for diagnostic purposes.

The emotionally disturbed are more sensitive to the dream, since dreams are, more often than not, disturbing to them. Discovery of the repression of dreams or of parts of dreams or the recall of specific sections of a dream can be of help in the assessment of the patient's mastery of his internal conflicts. Of particular significance is the repetitive dream, which affords evidence of a long standing conflict and aids in the reconstruction of those events that may have contributed to it.

The absence of dream material in the early evaluation of children may stem from the hesitancy to explore such an intimate part of the child's life as his dreams and fantasies. It has been noted that there is a reluctance on the part of the clinician to ask children about their dreams during the early interviews, in spite of the evident readiness of many children to speak about them.

The mechanisms of the dream show that uncon-

scious processes appear to be able to dispense with time and with the link between specific events and space. Condensation, displacement, substitutions, and symbol formations are distortions of reality, but they provide insights into the processes of unconscious psychic life.

Physiology of Dreaming

Over the last years, significant contributions have been made in the physiological aspects of sleep and dreaming. These findings indicate that dreaming is as necessary for the individual as sleep, and that the dream state should be considered separately from the biological conditions of sleep. It was found that the dream-sleep ratio is quite stable among adults. In adult life, 20 per cent of sleeping time is given to dreaming. The data accumulated show that, even in newborns, there is brain activity that is similar to the dreaming sleep. But it is doubtful whether dreaming is possible before speech—that is, before the existence of mental representations of the outside world.

Periods of rapid eye movements (REM) take place about 60 per cent of the time during the first few weeks of life; between 14 and 20 weeks, the figure is 40 per cent; around the end of the 1st year of life, it drops to 40 per cent of the total sleep time; by 24 months, these REM periods occur regularly and are uniform in length; between 3 and 4 years of age there is a marked reduction to 20 per cent; which is close to the adult ratio. All this indicates the importance for children of that state in life in which dreams occur and indicates the major role that dreams play during the early years of life. Further findings that REM or dreaming sleep is frequently accompanied by penile erections open up new possibilities for the correlation of dream content and biological processes.

Suggested Cross References

For further information on the physiology and clinical correlates of sleep and dreams see Section 2.4 in Area B, on the basic behavioral sciences. Chapter 6 contains a more detailed discussion of the psychoanalytic technique of dream interpretation used in the treatment of adults.

COMMUNITY AND SOCIAL PSYCHIATRY

It is particularly appropriate that one of the final areas in this textbook should be devoted to community psychiatry. For the very structure of the volume has thus been emphasized. The basic behavioral sciences form the foundation of the edifice—and of the discipline it houses. And the edifice, as well as the foundation on which it rests, is strengthened and enriched as new “floors,” representing theoretical and therapeutic advances, are added to the structure. The floors which have been added to the structure most recently derive from the field of community psychiatry. These floors are in various stages of construction: some were completed only recently; others are being erected now, and still others are presently in the planning stage. Community psychiatry clearly constitutes an emerging field which, in fact, has not yet been defined precisely.

In the circumstances, a brief account of the historical evolution of this important subdiscipline may help to orient the reader to the content presented herein. In the general introduction to this volume, the editors emphasized the relevance of philosophical and socioeconomic developments in American history for the application of psychiatric theory. The history of community psychiatry clearly demonstrates the validity of this hypothesis. Thus, although Adolf Meyer recommended the establishment of the community mental health center some 50 years ago, the Great Depression of the 1930's and World War II provided the stimuli which led to the implementation of this recommendation. During the 1930's the concept that the government must bear a major share of the responsibility for the amelioration of social and economic stress gained increasing acceptance, and the social legislation which was enacted as a result, reflected this concept of collective responsibility. World War II, in turn, revealed that a large proportion of the population was

unfit for service in the Armed Forces because of a wide range of personality problems which either were apparent at the time of induction or became evident under combat. Thus, the profound concern with the mental health problems of society might be viewed as an inevitable outgrowth of the commitment of the 1930's, coupled with the awareness, gained during the 1940's, of the prevalence of mental illness.

At any rate, this concern continued to gain momentum. When, at the conclusion of World War II, the New York Academy of Medicine decided to initiate a series of lectures on the subject of medical experience in the War, it designated “Problems of Psychiatry and Human Behavior” as the theme of the first lecture in the series. In support of this decision, the President of the Academy issued the following statement: “The Committee lays pointed emphasis upon the fact that by far the greatest lesson which the War has taught, far greater in its significance for humanity than either atomic energy or the control of the infectious diseases, has been the recent revelation of the magnitude and multiplicity of the disorders of human behavior.”

The postwar concern with mental health culminated in the Community Mental Health Centers Act of 1963. In the years since, we have had an unusual opportunity to observe at first hand the influence of major social and political concerns on the field of psychiatry and, concomitantly, the influence of our professional concerns on legislation and society in general. The implications of this reciprocal influence for social progress, as well as for the progress of this discipline, bring community psychiatry to the forefront as a field which commands the attention and the talents of psychiatry.

Unfortunately, our efforts in this connection have been seriously hampered by the lack of consensus as to the function and scope of community psychiatry and community mental health programs, as to the specific

professions which are best qualified to participate in such programs, and on the extent of their participation. The sections included in this area deal with each of these issues either directly or by inference.

Caplan and Caplan have "set the stage" for this presentation by delineating the basic concepts of community psychiatry and tracing their historical development. Leighton and Leighton have recounted some of the pertinent studies in this field.

The function and scope of community psychiatry have been dealt with specifically from diverse viewpoints. Bertram Brown has identified those factors which have interfered with our efforts to delineate the function and scope of community psychiatry with some degree of precision. On the other hand, the section by Yolles, which consists of a "concrete" description of the United States Community Mental Health Program, might be regarded as a positive approach to this question. Similarly, the sections on primary, secondary, and tertiary prevention by Visotsky, Berlin, and Freedman, respectively, as well as Brotman's section on treatment of the impoverished, provide important potential guidelines for precise formulation of the function and scope of community psychiatry.

Finally, the nature and extent of professional participation in community psychiatry have been discussed by Greenblatt in two separate sections. The first of these focuses on mental health consultation; the second is concerned with the role of the community mental health worker.

Presumably, clarification of these major areas of concern will permit formulation of a satisfactory definition of community psychiatry and community mental health. The view stated by Brown in his section on the definition of mental health and disease is relevant in this connection. Specifically, while Brown is aware that mental health cannot be defined unequivocally at present, he maintains that this concept will be delineated gradually, concurrent with the over-all development of the field.

At times, the lack of agreement with respect to the "crucial" issue of definition has been cited as proof of the confusion which pervades this subspecialty. In fact, however, difficulty in definition should be regarded as an inevitable concomitant of a newly developing field. As experience and knowledge increase, definitions and structures will be discerned, and techniques and procedures will become institutionalized. One might even speculate that the present state of flux offers certain advantages, in that it provides opportunities for originality and creativity which may not be available once petrification has set in. In any event, there is little doubt that community psychiatry will be the burgeoning field of the late 1960's and early 1970's. This prediction, in itself, precludes premature, unqualified acceptance of what has been written or implemented to date, and, by the same token, it points up the importance of an "open mind" and eager anticipation of future developments.

Chapter 45

Community Psychiatry. I: Basic Concepts

45.1 DEVELOPMENT OF COMMUNITY PSYCHIATRY CONCEPTS

GERALD CAPLAN, M.D.

RUTH B. CAPLAN, B.A.

Community Psychiatry denotes the body of knowledge, i.e., theories, methods, and skills in research and service, which is required by psychiatrists who participate in organized community programs for the promotion of mental health, the prevention and treatment of mental disorders, and the rehabilitation of former psychiatric patients in the population. It supplements the clinical knowledge and skills which equip the psychiatrist to diagnose and treat his individual patients.

In this section we will discuss the main historical factors which have influenced the development of concepts of community psychiatry in the United States during the 20th century. We will then summarize current views on the essential elements of these concepts, discuss present day problems of terminology, and conclude with a brief note on the roles and responsibilities of community psychiatrists.

Historical Background

Overview. The concepts and practices of community psychiatry have been evolving for over half a century, and the manner in which various issues have been resolved during this time has led to the present orientation of the field. One such issue has focused on the extent to which psychiatrists perceived their responsibility toward the community, and the corresponding expectations of the general public. The nature of such obligations and expectations has depended, in large measure, on current theories of the etiology of mental disorder and on professional and popular attitudes regarding the efficacy of therapeutic and preventive programs. A second related issue has centered on the isolation of psychiatrists in remote

custodial institutions or within the walls of private offices, as opposed to their daily participation in community contacts within the core living space of the population, where they are exposed to the immediate impact of community pressures and the challenge of developing new ways of dealing with a diverse patient population in collaboration with other community care-givers.

Theoretical basis. At the turn of the century, psychiatry was in a state of transition. There were few alienists in this country, and the majority of these practiced in asylums for the insane, where they shared the isolation of the inmates. In fact, the scientific status of psychological medicine was low, not only in the eyes of the general public, but in the opinion of other medical specialties as well. The Presidential Address to the American Medico-Psychological Association delivered by P. M. Wise in 1901 to an audience of about 100 members and friends, mirrored this situation. In his speech, Dr. Wise made a plea for the respect and collaboration of fellow physicians and academic psychologists; he attempted to justify this claim for recognition by citing the scientific advances in psychiatry during the preceding half century with regard to the cause and management of mental illness.

The somatic theory of mental illness. At the beginning of the 20th century, psychiatrists subscribed to one of three theories as to the nature of mental illness. One of the dominant groups believed in the somatic origin of all such disorders. According to this view, mental illness was not an independent disease of the mind, but a symptom of an organic condition, such as brain lesions, endocrine imbalance, or a metabolic disturbance. In spite of its rational and scientific mien, in a sense, this theory had its origins in the deep religiosity of such 19th century psychiatrists as Pliny Earle, to whom the possibility of an independently corrupt intellect was unthinkable, since this would violate the doctrine of the immortal soul. Another influence was that of German psychiatry, particularly the nosological concepts of Kraepelin, who was interested not in the specific personality disorder of a single patient, but in categorizing the general symptomatology of

psychoses. It was due to the work of such scientists that psychiatry began to seem a real part of medicine, with circumscribed diseases and categorizable syndromes of symptoms, with diagnoses and prognoses. And in the United States it was this group which eventually managed to unite the American Medico-Psychological Association with the American Congress of Physicians and Surgeons in 1903, thus helping to end the previous organizational isolation of psychiatry from the rest of the medical community.

On the other hand, with regard to prognosis, this was a highly pessimistic school which offered little hope of recovery. Its adherents saw their role as providing isolated and fortified custodial institutions to house the unwanted and feared multitude of insane persons from public view and conscience. The members of the organic school seldom ventured into the community unless they were asked to testify in criminal trials. If, for one of a variety of political reasons, an alienist lost his hospital appointment, he might establish a private practice in neurology until a new institutional position could be found. In the early years of the 20th century, some of the most important contributions of this group were in biological research. And, eventually, individual workers tended to use selected patients in investigations of various treatment regimens, thus removing them from a huge, anonymous body of neglected inmates.

The hereditary theory of mental illness. Closely allied with this group were those who preached an applied Darwinism. According to this view, insanity was a hereditary taint which was Nature's way of casting off weak and defective members of the race. The clock of evolution was "speeded up," so to speak, so that nervousness and excitability in one generation could lead to "raving mania" by the third. Environment was seen to play a part in such degeneration, as it did in every Darwinian scheme. It was felt that those individuals whose brains were not fully developed were casualties of the complexity, speed, pressure, temptations, and frivolous literature of civilization to which they were unable to adjust. In 1904, an English alienist surveyed the apparently rising rate of insanity in London and predicted a similar and ever growing increase in mental illness in other industrial and urban areas. He found grim consolation, however, in his belief that city dwellers become sterile after the third or fourth generation, so that the flood of new cases could not last indefinitely. Salvaging the children of these degenerates was felt by some to be a futile task, since it would be impossible to counteract their tainted genes by education and healthy environment in less than two or three generations; it was, however, possible to protect the race by two forms of prophylaxis: the control of immigrants, who presented an alarming number of disorders, and eugenics.

Preventive concepts. In response to public pressure, an Immigration Act was passed in the United States in 1903 which excluded those who had been mentally ill up to 5 years before their application to enter this

country and authorized deportation of those persons who broke down within 3 years of their arrival. It was also felt by leading psychiatrists that public education and laws were necessary to prevent the mating of undesirable individuals who would only produce a growing number of public charges. This recommendation was supported by the results of surveys, such as the Jukes-Edwards and the Kallikak studies, comparing families of degenerates with the descendants of upright citizens. After these data were made public, laws were enacted in several states permitting the sterilization of the mentally retarded and of some types of criminals. Thus the concept that mental disorders might be inherited was apparently taken very seriously by many in the population. As part of his Presidential Address before the American Medico-Psychological Association in 1903, in which he made a strong plea for eugenics, G. Alder Blumer read a letter from a maiden lady in which she had written that she was pleased to learn of the advances in the kindly treatment of the insane, for, since several of her relatives had died of "softening of the brain" and similar maladies, she knew that she was destined for a similar fate and was consoled to think that she might expect some comfort during her own decline. The theory of hereditary insanity, although it undoubtedly burdened many such frightened laymen, served to give psychiatrists a sense of their own responsibility as guardians of the public sanity. Moreover, it brought them in contact with the public, insofar as they could engage in education and exhortation.

The sociocultural theory of mental illness. A third view contained aspects of the other two theories, admitting certain somatic and hereditary conditions, but emphasized environment, culture, and education, rather than bodily traits alone. Its adherents tended to focus on the symptoms of the individual patients, rather than concentrating on the disease itself as the primary topic of study. One of the more interesting of these positions was adopted by those workers who, wearying of the nosological controversies which were prevalent prior to the First World War, maintained that mental disease was not a distinct entity with independent causality at all, but was rather a deviation from a reality-based norm of behavior which could be precipitated by cultural, socioeconomic, and personal idiosyncrasies. Therefore, every case, unless it was a bona fide example of epilepsy, mental retardation, paresis, or some other obviously organic complaint, was to be considered in its own terms, and not stereotyped by a general and possibly meaningless categorization. Concurrently, psychiatrists began to make use of social workers to gather information about the family, as well as the occupational, and educational background of their patients, in the hope that it would shed some light on the causes of the disease, on the possible course of treatment, and on changes in the environment which might be advisable before the pa-

tient returned home. At the same time, treatment programs began to include occupational therapy, short courses of formal education, rational conversation, milieu and habit therapy, and other social methods in the cure of patients.

Preventive concepts. The adherents of this third view were highly concerned with prevention, sound treatment, and after-care. Some doctors noticed, for instance, that such scourges as alcoholism and general paresis seemed to occur mainly among members of particular ethnic groups, and rarely among others. Leaders of American psychiatry, such as Adolf Meyer, felt that prevention might be possible if these target populations could be educated to the dangers of these diseases, and if restrictions could be placed on houses of prostitution and on the sale of alcohol.

The belief that insanity was caused by harmful influences in the family or in the wider environment led psychiatrists to conclude that if these influences were forestalled, or if there were a change in the individual's environment, the disorder might be checked. Thus, they stressed the importance to the prospective patient and his family of seeking therapy in time to limit the personal and social damage of the illness. Since fearful stereotypes of mental disease and mental institutions often prevented the mentally ill and their families from applying for professional aid, some psychiatrists were particularly anxious to dispel public ignorance, misconceptions, and prejudice. To this end, they supported a new venture in the education of mental hospital nurses, for example, which would provide them with general training, so that when they left a mental institution they would be qualified to work in a general hospital, where they could spread realistic reports of institutional conditions. Similarly, the services of psychiatrists were exposed to public view through the establishment of psychopathic hospitals and wards and out-patient clinics or dispensaries.

The therapeutic concepts. Psychopathic hospitals and wards in major cities, such as the Boston Psychopathic Hospital, the Insane Pavilion at Bellevue in New York, and Pavilion F at Albany Hospital, offered refuge and emergency care for acute cases brought in by police or relatives. These patients were detained for an average of 5 days until it could be ascertained whether they required hospitalization elsewhere or were eligible for discharge. Psychopathic wards in city hospitals frequently provided an alternative to prison for alcoholics, epileptics, etc.; they provided a convenient central institution from which distribution could be made to distant and isolated mental hospitals with less inconvenience to the patient's family and friends; and they provided a safe-guard for those who did not need long term hospitalization, and who were thus spared the stigma of commitment. Out-patient clinics or dispensaries, like the one established in 1897 by Walter Channing in Boston, were designed to provide clinical experience for medical students, as well as treatment for patients in the early stages of disease.

It was hoped that prompt intervention would prevent further disturbance in patients who were undergoing an acute, but transient, emotional crisis, and cure more serious cases faster and more successfully than was possible when these patients entered a mental hospital as a last resort.

Implications for community psychiatry. A refrain runs through the writings of many of these physicians that there was an important future for psychiatry outside mental hospital walls. In 1909, for instance, Adolf Meyer visualized an entire community mental health program in which the various overlapping jurisdictions of such care-giving agencies as schools, police, and welfare could be unified into a single district containing a mental hospital. It would then be possible to conduct an integrated program of prevention, treatment, and after-care of mental disorder, with the psychiatrist in the hospital working in concert with teachers, police, welfare workers, and general practitioners in the community. Meyer also advocated the immediate implementation of a plan to involve family doctors in the treatment of hospitalized psychiatric patients. Presumably, this would maintain the interest of the general practitioner in a case which he might have to manage after discharge; it would also help to reduce his ignorance and fear of institutional life, so that he might realize the advisability of committing other patients before their illness became chronic. Thus, Meyer suggested that the family doctor be invited to tour the mental hospital, and that he be invited to attend staff meetings at which his patient was discussed. If he was unable to attend, he might be asked to submit a report of his experience with the patient, and the minutes of the staff meeting would be sent to him, in turn. Meyer also suggested that literature on conditions at the institution, commitment procedure, therapeutic developments, etc., be prepared periodically and distributed to general practitioners. He also advocated a program of public education to reduce the stigma of mental disorder and to develop mentally healthy attitudes and habits. He addressed many lay groups and often illustrated his thesis that insanity should not be a cause for shame by talking openly about the mental illness of his own mother.

Public education has remained a central issue in community psychiatry. Originally, it was felt that a more sophisticated population would probably be healthier mentally; that is, greater understanding of one another's needs and greater tolerance for deviations of behavior would reduce the incidence of mental illness. Such education should lead to improved methods of child rearing and to healthier ways of mastering life's problems. A second but not less important goal has been the enlistment of public support and the cooperation of civic leaders for the improvement of community facilities for the mentally ill.

Historical antecedents of community psychiatry

The mental hygiene movement. The movement of psychiatrists into the community was accelerated not

only by the development of professional theory, but also by the demands of the lay public. Clifford W. Beers in 1905 published *A Mind That Found Itself*, an account of his experiences as a patient in three mental hospitals in Connecticut. His book gained wide circulation and aroused much interest among laymen and doctors. This was a call to reform in the lay social action tradition of Dorothea Dix and Jane Addams. Like these great social reformers, Beers was inspired not merely by a desire for revenge against his tormenters, but by a humanized Protestantism current in the 19th and early 20th centuries. This movement, spreading out of New England, retained the traditional fervor and intensity of Puritanism, but substituted an ideal of love for man's fear of God. This extended into the temporal sphere, where it produced a feeling of duty toward the suffering and weak of humanity so intense that it transcended any possible diffidence that might arise in the face of complacent professionalism. All during the history of the mental hygiene movement, leadership was shared, not always harmoniously, between laymen and professionals. Lay involvement was evident not only among individuals actually working in the organization and among non-psychiatric professionals participating in its program, but also among the many foundations and philanthropies which have financed its operations for nearly 60 years.

Philosophy. In 1908, Beers and a distinguished group representing medicine, both general and psychiatric, law, religion, and education founded the Connecticut Society for Mental Hygiene, which was followed in 1909 by a National Society. The mental hygiene movement, led by such psychiatrists as Meyer, Salmon, Frankwood Williams, and many others, was greatly influenced by the concepts of public health. It recognized that modification was necessary in the traditional role of the psychiatrist, just as it had been in that of the public health physician. Emphasis was now to be shifted from a single patient seen during a single, temporary episode, to the superintending of the mental health of an entire community over an indefinite period of time. The Society viewed such a community as composed of individuals whose mental health was impinged upon by a variety of biological, social, and environmental factors. The Society thus identified its primary goal with that of the public health movement, in prevention as well as in cure, and in the prompt detection and control of unhealthy forces and of incipient maladjustment by means of research, legislation, all embracing community services, and public education. As C. E. A. Winslow, Professor of Public Health at Yale, and president of the Connecticut Society said at the 25th anniversary meeting in 1933, "It is an organized community response to a recognized community need."

Program. From the first, the mental hygiene movement was remarkable for its attempts at basic and realistic planning. During its first few years it col-

lected and distributed data on the standards of care and treatment of mental disease and of mental retardation; on the manpower needs, resources, and education of mental health personnel; and on mental health needs among the school age population. On the basis of such data, it was hoped that sound programs could be devised, and appropriate institutional growth, legislation, and budgeting could be instituted.

Military psychiatry. One of the early and most critical of these planning attempts was carried out by Thomas W. Salmon and his associates just before the United States entered the First World War. The rate of mental health casualties was examined among Americans troops on the Mexican border and among British soldiers in the French trenches. On the basis of this information a plan was presented to and approved by the Surgeon General for the prevention and treatment of mental disorder in a population soon to be at serious risk. The plan itself included a selection process to exclude obvious risks, such as the psychotic and the mentally retarded; assignment of psychiatrists to each of the services; a system of immediate treatment of mental casualties as close to the front as possible, with a continuing plan of treatment at major hospitals abroad, at ports of embarkation and disembarkation, and at hospitals in the United States.

Although this plan was doomed to inadequate implementation because of a serious shortage in manpower, the war marked several advances in community psychiatry. It aroused a great deal of public concern about mental health and rehabilitation and it dispelled some feelings of stigma and stereotype; it counteracted vestiges of the view of exclusively somatic causality, a view which was reflected in the term "shell shock," but which was removed in later terms such as "war neurosis" or "war shock." It forced the use of nonprofessionals in the effective control of mental disease; it encouraged the use of short term therapy, such as hypnosis, to remove hysterical symptoms in one session, and short term psychotherapy by suggestion and persuasion, such as that devised by Ross in England; and it encouraged the early use of group methods. It also stimulated advances in manpower education, particularly that of psychiatric social workers, for whom a school was opened at Smith College in the summer of 1918. After the war the records of the psychiatric experiences were gathered into one volume of the Surgeon General's Report, where they were unfortunately to be completely forgotten until the middle of World War II.

The child guidance movement. After the war, mental hygiene broadened its operations once more, reflecting lay and professional enthusiasm. One of its most hopeful ventures was the child guidance movement which began in the 1920's under a grant from the Commonwealth Fund. It marked a development from the work of William Healy in Chicago and Boston, and from the interest of child study groups. It also reflected the influence among laymen and psychiatrists of the

theories of Freud and his followers, that mental disorder in an adult is a consequence of unsolved psychological problems, faulty personality development, and mismanagement of children.

Philosophy. The child guidance clinic was envisaged as the key to the prevention of mental disorder in a population. It was thought that childhood disorders might be cured far more quickly and effectively than those of an adult; thus it was hoped that prompt care at this stage would stop the flood of adult patients into mental hospitals. The child guidance clinic was also seen as a center which would disseminate proper attitudes and child-rearing techniques among parents and teachers in the community; provide much needed training facilities for young professionals; and furnish a tactical and economical way of using a desperately inadequate number of professional workers for the maximum benefit of the community.

Program. The success of these clinics was mixed. On the one hand, they did provide a setting for the study of the diseases of childhood; of the complex physical, psychological, and sociocultural forces contributing to such diseases; and of areas of diagnosis and treatment. Research was carried out into many factors which modify the healthy and unhealthy environment of the child, such as his relationship with his mother and with other family members. The clinics developed the use of the psychiatrist-psychologist-social worker team, each member of which contributed his own viewpoint to analyzing the problems of the child and his environment, and each of whom further developed professional tools for the new setting: individual and group psychotherapy methods, intelligence and projective personality tests, and social and developmental history interviews and casework techniques. There was also a greater use of psychoanalytic concepts regarding unconscious elements in the child and his relationships with those around him by all three groups of professionals. The clinics provided the hoped for training facilities for young professionals, many of whom then went on to develop in-patient services and preventive community programs.

On the other hand, the clinics ran into serious difficulties and frustrations which made it plain that the original goal of eventually reducing the rate of adult disorder by the treatment of children was far more distant than the founders had anticipated. In practice, the assumption that a child was easier to treat than an adult was not borne out. Even young children required a lengthy expenditure of professional effort by the time they were brought to the clinic, particularly as the enthusiasm for psychoanalytically-oriented treatment and casework techniques demanded an increase in professional time for each case. Second, the promotion of early case finding by referrals or screening in schools meant that far more cases were uncovered and labeled as disturbed than could be treated. Because of this, and because of demands for services from other professional agencies and from the public,

clinics developed long waiting lists and the habit of shuttling "unsuitable" cases from agency to agency, all of which caused friction with the community. The clinics also developed stereotyped functions for each member of the team, and internally oriented standards of achievement such as properly written reports, full batteries of tests, meticulous supervision of junior staffs, orthodox psychoanalytic techniques, etc., all of which served to orient the clinic inward toward its own craft performances, rather than outward to the needs of the community. Instead of the public health focus on the total population, as had been the original dream of the mental hygiene movement, the clinics slipped back into the traditional clinical pattern of dealing exclusively with a relatively small number of individual patients. Other problems included the disillusionment of many child psychiatrists with the preventive value of parent education. This had originally been a key element of the clinics' function but was now seen as inadequate when more emphasis was placed on depth psychology. This served to break another link with the community, so that little attempt was made to contact the public for other than public relations purposes.

Assessment of progress in prewar mental hygiene efforts. During the 1920's and 1930's mental hygiene was frequently attacked for its apparently grandiose and utopian vision. Critics felt that its enthusiasts treated their programs as panaceas for the prevention of mental deficiency, criminality and delinquency, the psychoneuroses, the psychoses, anti-social traits, divorce, prostitution, alcoholism, sexual perversion, epilepsy, war, and all other ills. Some detractors, such as Gregory Zilboorg, questioned the efficacy of the many educational ventures of which the movement was so proud, casting doubt on the value of intellectual understanding in an emotional area. Others, such as Kingsley Davis, saw mental hygiene as a social movement which had adopted as its ideology the Protestant ethic. This ethic was being imposed on a sometimes unsuitable population as advice in the conduct of personal affairs and, furthermore, was the unconscious source for a supposedly scientific analysis of mental concepts. Davis felt that the mental hygienist had become an outmoded moralist in a scientific world.

Changing theoretical orientation. In spite of the sober stand of such men as Adolf Meyer, who advocated careful experimentation and analysis, and then implementation with reference to real conditions, some of this criticism had a valid basis. The mental hygiene movement, like certain other social, political, and religious groups in the 1920's and 1930's, was highly critical of the failings of modern society and felt that a manipulation of the social, economic, and political environment would alleviate most of the ills of humanity. Labor unrest, crime, dependency, etc., were seen to be evidence of bad mental hygiene, which could be cured by approved mental hygiene techniques. This

view was by no means a new one; Edward Bellamy in *Looking Backward*, written in 1887, recorded that in his ideal society of the year 2000, freed from all labor strife, economic exploitation, money, class barriers, charity, dependency, and wars, nearly all insanity had disappeared. Perhaps one of the best known of these formulations was that of Lawrence K. Frank in *The Society As Patient*, in which he suggested that instead of dealing with each mental and social maladjustment as though it were an independent category, a somewhat simpler and more manageable model might be to think of society itself as being sick, and of these individual cases as its symptoms. Therefore, instead of treating thousands of symptoms, it might be more effective to cure the disease at its source.

Relevance for community mental health. Such theories marked an important stage in the growth of community mental health concepts. They showed the willingness of mental hygiene workers to see the boundaries of their effectiveness indefinitely expanded to include all aspects of human life. These boundaries no longer included just individual patients, or even the entire sick population, but were extended to include those who might be quite normal, but whose effectiveness could be increased a little more until they functioned closer to their full potential. Such ideas implied an eagerness to cross professional boundaries, to cooperate with teachers, clergymen, judges, police, politicians, etc., in order to ameliorate every aspect of the environment.

There were, however, two pitfalls in such a course. The first was the tendency to excite too much public enthusiasm and overly optimistic expectations so that professionals were often carried beyond the limits of validated theory and of existing services into areas where risks were high, as when they identified more cases among the school age population than could be treated in the early days of the child guidance movement. The second pitfall was the tendency to turn other professional groups into less qualified psychiatric workers, thus endangering their own professional identity and function and producing an often clumsy amateur therapist. This could perhaps best be illustrated by early attempts to include some kind of mental hygiene instruction in schools, which sometimes turned classes into group therapy sessions with the children being encouraged to reveal their fears, conflicts, and feelings of inadequacy and guilt by a teacher who might not always be able to handle safely so unpedagogical a situation.

This was perhaps a necessary transitional stage in the growth of psychiatry in the community. It showed an inability yet to recognize that the independent professional functions of other disciplines are capable of leading to the fostering of mental health quite independent of current psychiatric thinking, as when a good teacher *qua* teacher promotes mental health unconsciously by the competence with which he handles his class and presents his material, without needing

recourse to instruction in mental hygiene techniques. Under these circumstances, psychiatry was not yet moving out into the community to assess needs and to provide corresponding services. It was instead imposing preconceived ideas on others, setting up its own criteria of good, and drawing other professionals in, not to improve the mental health aspects of *their* work, but to make them the adjuncts in carrying out the psychiatrist's own, self-appointed task.

Obstacles to progress. These pitfalls may provide a clue to the weaknesses of mental hygiene prior to the Second World War. Many of the ideas of its leaders have a surprisingly contemporary ring, like the plan of Adolf Meyer for comprehensive community services which would integrate a central and accessible mental hospital with the services of other care-giving agencies in a joint catchment area. One wonders why such schemes were not carried out 30 or 40 years ago, and why similar projects are still considered revolutionary in the mid-1960's.

One may hazard several guesses on why many of these plans did not progress beyond the speculative phase. First, there was a lack both of psychiatric manpower and of training facilities and funds, although attempts were made to remedy these conditions in the 1920's and 1930's by the improvement of psychiatric instruction in medical schools and by the granting of training fellowships by the Commonwealth Fund and the Rockefeller Foundation in 1923 to be administered by the National Committee for Mental Hygiene. The lack of personnel meant that most practitioners were fully occupied and often overwhelmed by their traditional roles of treatment and of mental hospital administration. Moreover, many of the bright young men of the 1920's and 1930's were engaged in another new and promising venture in American psychiatry, psychoanalysis, which drew them away from community matters into the privacy of their offices.

Second, there was a lack of knowledge of the nature of specific threats to mental health so that plans for prevention were necessarily vague and global, since it was difficult to locate and isolate populations at risk. This vagueness lent a utopian quality to many statements of the mental hygienists. Today, after research has been conducted which indicates a basis for some of their assumptions, it is possible to make specific recommendations for ameliorating particular harmful conditions. For instance, some mental hygienists held that labor unrest was a sign of mentally unhealthy conditions in industry which should be corrected by changes in the policy of employers toward their workers. John R. P. French has recently reviewed studies carried out over the past few years which have shown a high correlation of mental upset, and particularly of psychosomatic conditions, with low status in industrial jobs. He has suggested that specific modification of the social environment and the industrial structure might be practicable which would relieve some of the more onerous characteristics of low status, such as lack of

self-esteem and a sense of powerlessness over the conditions of the job, thus preventing these forms of mental upset.

A third obstacle may have been the lack of development of adequate theories and techniques of community work, and a corresponding paucity of research. This was again due to a lack of personnel and of research funds, and also perhaps a lack of willingness among many psychiatrists to engage in an area so far removed from their professional training. Moreover, there was as yet little collaboration with the experts in community research, the social scientists. Thus, in spite of the admonitions of leaders like Adolf Meyer to plan community services which would correspond to real conditions, this was to prove extremely difficult in the absence of techniques to observe and assess possible obstacles such as political pressure groups, vested interests, the probability of arousing more demands for services than could be satisfied, or the possibility of proliferating services which psychiatrists thought appropriate, but which did not, in fact, satisfy the current public need. There was as yet no real appreciation of the ignorance of psychiatry in community matters, and consequently, flexibility was not maintained in programs to allow evaluation and modification as experience demonstrated their inadequacies. There was instead the rigid digging in and progressive isolation in the face of community pressures of such agencies as child guidance clinics.

The fourth problem may have been a lack of public interest in and motivation toward such community approaches. Laymen, and particularly legislators, who thought of psychiatry in terms of traditional institutional therapeutic services, were unwilling to appropriate funds for these new ventures.

Many of these obstacles would, however, be modified by the upheavals of war, with its demands for dealing with army populations, and with its massive mobilization and concentration of manpower and resources which suspended traditional roles and relationships for a collective, overriding goal.

The Second World War. When World War II broke out, farsighted psychiatrists, such as those in the William Alanson White Foundation, were concerned about forthcoming threats to mental health. They saw their task as maintaining civilian and military morale; implementing an effective screening process during recruitment and training; instituting prompt treatment of psychiatric casualties at the Front and rehabilitation of both returned casualties and those screened out of the army on psychiatric grounds; and maintaining mental hospital standards. However, for the first 2 years of war, efforts were pitifully inadequate. There was still a major shortage of professional manpower, with only about 3,000 psychiatrists in the United States to serve both civilian and military populations; thus each psychiatrist at recruitment stations often saw 200 cases a day. Psychiatric leadership was divided and indecisive, and unlike Salmon and his associates in

World War I, they seldom initiated negotiations with the authorities in order to promote their own participation. This diffidence of psychiatry was matched by the indifference of civilian and military leaders to the possible contribution of mental hygiene. It was not until 1942 that the Army Medical Corps set up a neuropsychiatric branch, first under the leadership of Roy D. Halloran and later under William Menninger, and appointed psychiatric consultants to each of the service commands; it was later still before psychiatrists were assigned to each army division. Mental health programs were further hampered by a lack of knowledge not only of the causes and cures of disorders, but also of methods for dealing with such large populations. As mentioned above, the records of psychiatric experience in World War I, which had been collected into one volume of the Surgeon-General's Report, were completely forgotten by everyone until the middle of World War II, so that much valuable guidance was lost.

The war, however, did mark a number of advances. It gave psychiatry firmer support among civilian and military leaders, and a status closer to that of other medical services. It taught psychiatrists more about neuroses, and particularly about psychosomatic disturbances. It encouraged the use of short term manpower-saving treatments, such as group therapy and narcosynthesis. The Veterans Administration hospitals were reorganized with more modern programs of rehabilitation and research. Such hospitals also reduced their own isolation from the community by the use of volunteers and by organizing out-patient clinics. The war emphasized the importance of morale and leadership in any preventive program, particularly in large organizations such as colleges and industry; and it helped to teach psychiatrists in such institutions not to look only at an individual case, but to recognize overriding group aims and needs.

Postwar developments. After World War II, psychiatrists returning to civilian practice in Britain and the United States attempted further to break down their traditional isolation from the public by adapting the progressive and flexible practices developed in the armed services to the needs of civilian life. Frustrated by the lack of leadership and by the conservative attitudes of the professional establishment, these more activist physicians formed organizations of their own whose members continue to develop and promote the concepts of community psychiatry. The Tavistock Clinic was reopened in London under the leadership of J. R. Rees where emphasis was placed on the amelioration of the work environment by consultation in industry, on the training of school teachers and general practitioners, and on the use of group and family therapy. In the United States, a number of "Young Turks" led by William Menninger formed the Group for the Advancement of Psychiatry (GAP) in protest against the conservatism and inaction of the American Psychiatric Association (APA). GAP has remained a

select organization whose members are divided into working committees, each of which concerns itself with a particular facet of the psychiatrist's role, either within the profession or in his relations with the community. These committees have studied such areas as the relations of psychiatry with government, religion, and law; the needs of adolescents, college students, and the aged; the responsibility of psychiatry in public education, in confronting social issues, and in the field of international relations; the evaluation of developments in therapeutic techniques, in medical education, and in the conditions of mental hospitals; and developments in child psychiatry, preventive psychiatry, and mental retardation.

Some of the early reports of these committees gave quite specific advice and encouragement to fellow professionals on approaching lay groups and addressing them on suitable subjects. Psychiatrists were warned not to use technical jargon and not to attempt to answer provocative or very difficult questions from the floor. Mental hospitals were encouraged to promote community interest in their activities and were urged to hire public relations experts.

GAP reports were circulated not only among psychiatrists, but also among lay groups, thus encouraging development and reform in such areas as industry and university health services, mental hospitals, and local community resources. GAP members and eventually other leading psychiatrists were also willing to speak out uninvited on psychiatric aspects of critical issues of the day such as segregation in schools and loyalty oaths.

It is significant that GAP members decided to retain their individual membership within the American Psychiatric Association as a progressive core, in spite of the fact that they also formed their own group. Since 1946, GAP members have been elected to the leadership positions of the APA, thus helping to alter the complexion of the entire profession. It is interesting that subsequently a group of mental hospital psychiatrists also formed their own organization, since they felt that the general meetings of the APA no longer represented their interest in institutional practice. As a sign of the times the title of their journal, *Mental Hospitals*, has recently been changed to *Mental Hospitals and Community Psychiatry*.

Current Developments in Community Psychiatry

Since World War II, many programs of research and service have been instituted which have extended the theoretical framework and methodology on which community psychiatry is based, thus filling some of the gaps that had weakened the earlier mental hygiene movement. These have included the following.

Advances in mental hospital practice. It has been increasingly realized that much of the traditional clinical picture of back ward chronicity has been due to hospitalism. This has stimulated a search for methods of reorganizing mental hospitals so that they might

function as therapeutic rather than pathogenic environments. Attempts have been made to improve the social structure and atmosphere of the wards, to introduce new methods of treatment, and to establish closer links with the community in order to prevent the isolation of patients from their social network.

The concept of the therapeutic milieu. New approaches to patient care in the United States have been influenced by the pioneer work of Europeans such as T. P. Rees, Maxwell Jones, Walter Bion, and John Rickman in England, and Paul Sivadon in France. They demonstrated the practicability of open wards and free communication between the hospital and its local community and developed the concept of "therapeutic milieu" in which increased communication among patients facilitates their mutual rapport, and in which participation of patients in decision making and control of behavior maintains and improves their ego strength.

These approaches were well received in this country. They meshed with current experiments in ward management then developing in such hospitals as the Boston Psychopathic, where Harry C. Solomon and Milton Greenblatt were already moving "from custodial to therapeutic patient care." The acceptance of these ideas was facilitated by a climate of increased reliance on methods of individual therapy which had developed during the past 3 decades from such techniques as fever therapy, insulin and convulsive treatment, to more recent use of psychotherapy and psychopharmacological agents. Such drugs were of particular importance in mental hospital reorganization, since by controlling behavior disorders and by reducing troublesome symptoms, much staff time previously spent controlling patients could now be freed for therapeutic efforts, and the patients themselves could be more quickly discharged to the community.

Administrative innovations. A major obstacle to developing administrative patterns conducive to a therapeutic milieu has been the large size of many institutions. Several American psychiatrists have been interested in a plan originally suggested by Sivadon, according to which hospitals would be divided into administratively self-contained units, each of which would provide facilities and staff for the total process of treatment and rehabilitation of a manageable number of patients and would allow continuity of care after discharge and in the event of future admissions. This unit system has facilitated the development of the mental hospital catchment area concept, each unit accepting responsibility for patients living in a limited geographic subdistrict. The unit staff is thus able to build and maintain relationships with a manageable number of community agencies and professionals who can collaborate in referral and after-care. This was previously impossible when all the staff dealt with patients indiscriminately drawn from the total area served by the hospital.

Over the past few years, mental hospitals have at-

tempted to reduce their own distance from centers of population and to minimize the alienation of patients from their social networks. Various patterns of transitional institutions have been developed in the community, such as day and night hospitals, halfway houses, therapeutic social clubs, sheltered workshops, etc., which have been designed both to reduce this isolation and to offer individualized patterns of care to suit the needs of patients at different phases of illness and recovery. Other attempts to reach out into the community and to reduce the risk of unnecessary or prolonged hospitalization have marked such programs as the Home Treatment Service of Boston State Hospital. These have been inspired by the work of Querido in Amsterdam, who developed a system of mobile psychiatric teams which visit new patients in their homes in order to decide whether they need hospital care, or whether they can be referred to outpatient clinics or other care-giving agencies.

Rehabilitation programs. Hospitals have also given increased attention to problems of rehabilitation. Many mental institutions have developed hospital industries, in which patients engage in realistic and productive tasks, often under contract to outside firms. Another approach is a series of programs conducted prior to and during the early stages of hospitalization which are designed to prevent the mutual alienation of the patient from his family, work, and social groups, and to inhibit the "closing of ranks" which would obstruct his eventual return. Hospital staff visit the home and work setting in order to interpret the patient's condition and prognosis to his social network, and in order to ensure maximum communication with the patient during his absence. Such programs have, however, encountered difficulties because they demand more community contacts than seem feasible for overworked hospital personnel. In some institutions attempts are being made to solve this problem through contracts between the hospital and a community-based agency such as a Visiting Nurse Association or the nursing division of a city health department. This may represent a pattern for the future in which a comprehensive service covering all phases of mental illness may be based upon collaboration between, and coordination of, mental hospital staff and workers in the community who will regularly visit each other's principal setting in much the way suggested by Adolf Meyer in 1909.

The community mental health center. These centers have become some of the major sites for developing, testing, and implementing community mental health concepts and techniques. Associated on the one hand with university departments of psychiatry, psychology, social work, public health, and social science, they have been the locus for much of the research in community psychiatry over the past 15 to 20 years, and they have acted as a focal point for the emergence of such techniques as mental health consultation, preventive intervention in life crises, and community

organization in relation to mental health. On the other hand, they have developed in close contact with their communities, working sometimes under local voluntary auspices, or, increasingly, functioning within the jurisdiction of state, county, or local departments of mental health, public health, or welfare. Many have grown out of child guidance clinics. Others, such as the Human Relations Service, opened in 1948 by Erich Lindemann in Wellesley, Massachusetts, were originally established with a preventive community orientation similar to the public health goals of the early mental hygiene movement. These have been updated by the addition of a community research dimension and by collaboration with social scientists and specialists in community organization.

By their close relationships with local civic leaders and with other community agencies and professionals, these centers have greatly increased psychiatrists' understanding of the sociocultural structure and functioning of community life. Greater sophistication has also been developed by the increased range of cases which such clinics encountered when they lowered administrative barriers, avoided the traditional waiting lists of child guidance clinics, and reduced stigma by effective public relations and by defining the goals of the center as ameliorating "adjustment problems" rather than as treating psychiatric illness.

Goals. The close link of many community mental health centers with public health, either because they have been established under public health auspices, or because members of their staff have been trained in schools of public health, has led to their adapting, with only minor modification, traditional public health practice concepts and terminology. Thus it has become usual for workers in these centers to see their major goal as prevention in community terms: primary prevention, reducing the rate of new cases of mental disorder in their population by reducing community-wide harmful influences, as well as cognitive and emotional education and the provision of services to help people at times of crisis, in order to promote the capacity of the population to deal with stress; secondary prevention, reducing the prevalence of mental disorder by shortening the duration of illness through early case finding and prompt effective treatment; and tertiary prevention, reducing the rate of residual disability following mental disorder by effective rehabilitation and by ensuring adequate follow-up care for the total population of ex-patients.

Operating principles. Another concept borrowed from public health is that of the catchment area, the geographically or institutionally bounded population to be served. This must be a manageable size so that subpopulations at special risk can be monitored and treated, and so that the pool of community care-givers and agencies is small enough for personal relationships to be developed between most of them and the specialists in the community mental health center.

Much of the work of these centers has been focused

on increasing the efficiency of the working practices of their staff and on developing methods which will produce chain reactions through the intermediation of other professionals, so that the specialists may spread their efforts as widely as possible in the community. To this end they have striven to avoid waiting lists. By seeing people during the acute disequilibrium of a life crisis or an acute exacerbation of a chronic illness, they are able to capitalize on the increased need for help and the heightened susceptibility to influence of the crisis state. Most of these centers have learned to restrict their intervention in the lives of their patients to a short series of psychotherapeutic interviews with the patient and his family during the few weeks of a crisis. This is consolidated by offering consultation to the general practitioner, clergyman, school teacher, recreation worker, or other care-giving professional to whom the patient is then returned for further care.

Mental health consultation is the most characteristic technique of community psychiatry to develop in these centers. It offers assistance to care-givers on the mental health dimension of their own work. In contrast to the methods of the early mental hygienists who tried to turn other professionals into the agents of the psychiatrist, this type of consultation maintains the role identity of the care-giver; and the psychiatrist restricts his communications to matters which increase the other's professional understanding and objectivity. Experience has shown the importance to the community psychiatrist of maintaining an egalitarian relationship with the consultee, since this allows the latter to make maximum use of the expert knowledge of the mental health specialist while retaining his own sense of commitment and responsibility.

The role of psychiatrists in community institutions and services. Because of their increased interest in working within the community, and because of a growing understanding by local leaders and administrators of their potential value, psychiatrists and their mental health colleagues have joined the staffs of many institutions and services. The experiences of the Second World War encouraged their use in government, industry, and colleges. Child guidance led to an interest in school mental health; and a number of school systems have employed their own mental health specialists. Psychiatric clinics have also been established in courts and in correctional institutions.

In most of these settings psychiatrists are unable to control their intake procedures by the traditional device of establishing waiting lists. They have therefore been forced to develop methods of stemming the flow of cases by offering consultation in order to modify the practices of other staff members and the operations of the social system so that problems are either prevented or are dealt with by others "upstream" in the early stages. These experiences are developing increased sophistication in consultation and collaboration and in methods of monitoring the transactions within the social systems of institutions.

The Peace Corps program. Of particular importance has been the development of a mental health program in the Peace Corps. Psychiatrists have been involved in this governmental organization since its inception. They were called in originally to help with the identification of mentally ill or unstable candidates who might break down overseas. They were then asked to participate in the selection of candidates with psychological attributes for particular jobs and to provide training to prepare all volunteers for the psychological and cultural burdens of overseas service. This led to involving the psychiatrists as consultants to the Peace Corps administrative staff and physicians to help them provide psychological support to volunteers in the field, so that they would be better able to handle the inevitable crises of adjusting to overseas conditions and to the "reverse culture shock" of returning home at the end of their 2 years' service. Eventually the Peace Corps leaders came to recognize the significance of the whole system of practices and working conditions of their organization for the adjustment and mental health of the volunteers and have involved their psychiatrists as consultants on general policy problems at all levels.

The special importance of this endeavor for the development of community psychiatry has been two-fold. First, the high prestige and visibility of the Peace Corps has attracted much interest to its novel use of psychiatrists as promoters of positive mental health and good adjustment, particularly as follow-up studies have demonstrated remarkably low rates of psychological breakdown in its stressful overseas operations. Second, its program has been mainly carried out by part time psychiatrists drawn from the faculties of most of the university departments of psychiatry of this country. These key people have had the opportunity of becoming involved in the "community" problems of Peace Corps selection and training camps, and in programs of primary prevention of mental disorder and the promotion of mental health in populations of healthy and attractive young people. This has exposed many of these well trained clinical psychiatrists for the first time to the problems and methods of community psychiatry and has aroused their interest in developing new knowledge and skills and in incorporating these in the educational programs for medical students and psychiatric residents in their medical schools.

Epidemiological studies. These are discussed in detail elsewhere in this chapter. Here we wish only to emphasize that during the past 20 years many studies of incidence and prevalence of mental disorders in a variety of communities have been carried out by multidisciplinary teams of psychiatrists, social scientists, and public health specialists. They have demonstrated ways of delimiting populations at special risk so that preventive or remedial action can be taken at the community level, and they have indicated ways of evaluating community programs by means of repeated surveys of experimental and control populations.

Interdisciplinary collaboration. Over the past 30

years, social scientists have shown increasing interest in research of direct relevance to community psychiatry, thus promoting closer collaboration between them and the traditional mental health professions. Studies have been conducted on small group interaction, social structure in mental hospitals, family relationships, attitudes to mental disorder, interrelations of the network of community agencies in the health and welfare field, leadership and morale, and many other subjects. These researches have provided a growing body of specialized theory to support the formulations of the community psychiatrist and to guide his appraisal of the salient factors which influence the mental health of his population and the development of his own program.

This research grew out of the collaboration between psychiatrists and social scientists which developed from the 1920's on, and which was most noteworthy in the career of Harry Stack Sullivan. Sullivan, with his theory of interpersonal relations as a primary factor influencing the genesis and therapy of schizophrenia and his work with small groups of patients in a controlled milieu, aroused much interest among social scientists. His first major contact with the latter probably took place in 1928 when he served as secretary of the First Colloquium on Personality Investigation, held under the auspices of the American Psychiatric Association, which was attended by such men as Edward Sapir, W. I. Thomas, Gordon W. Allport, Harold Lasswell, Sheldon Glueck, and L. K. Frank. Physicians present included William Alanson White, Arnold Gesell, and David Levy. At the Second Colloquium in 1929, W. I. Thomas, president of the American Sociological Association, suggested the need for a common meeting ground between psychiatry and social science such as a hospital residency for sociology graduates in Sullivan's program, similar to residencies developed for psychiatrists. The idea appealed to Sullivan, although it took several years to implement. In 1939, he founded the journal *Psychiatry* to serve as a forum for all branches of behavioral sciences. Sapir, Sullivan, and Lasswell also planned an institute which would fuse training and research in psychiatry and social science. This was embodied in the Washington School of Psychiatry in Washington, D. C., and in the William Alanson White Foundation of New York, named for Sullivan's great friend and the chairman of the First Colloquium. In the early 1950's, 20 years after Thomas' initial suggestion, a collaborative project was sponsored by the Washington School of Psychiatry. Morris S. Schwartz, a graduate of the University of Chicago Sociology Department, went to Chestnut Lodge Hospital in Maryland to work with one of Sullivan's students, Alfred H. Stanton, on a sociopsychiatric study of interpersonal relations on a hospital ward. Their findings were described in *The Mental Hospital*, a book which was the forerunner of many collaborative reports by social scientists and psychiatrists.

Family therapy. This method of psychotherapy has emerged mainly from the field of child guidance, with

its recognition of the diagnostic and therapeutic significance of the child's relationship with his mother and with other members of the family network. Interest was broadened to diagnosing and treating the family as a unit, since the difficulties of the referred child were seen as one sign of a general disturbance. Techniques derived from child guidance and from analytic group psychotherapy have been developed which represent one paradigm for the treatment of a social unit, in which the focus is on role relations in a social system and on patterns of communication and control, rather than on the individual treatment of one or all of its separated members. This has contributed to the development of new social system models to supplement our individual psychodynamic theories as a guide to therapeutic efforts.

Crisis and disaster research. A number of research programs have been focused on reactions of individuals, families, and communities to temporarily insurmountable stress experiences. These have ranged from individual transitions, such as the biopsychosocial developmental crises of puberty, pregnancy, birth, and climacterium; to accidental crises in individuals and families such as the onset of tuberculosis, birth of a premature baby, surgical operation, or death of a family member; to community stresses and disasters such as floods, tornadoes, and urban relocation. A body of theory is emerging from such studies which may be of great importance in preventing mental disorder, since it appears that the period of upset during crisis is a potential turning point when the individual's vulnerability to immediate or eventual disorder may change significantly. It appears that this depends upon his pattern of crisis adjustment, how he deals with the physical, psychological, and social tasks which are inherent in the situation. His way of grappling with the crisis is especially susceptible to influence by key persons in his social network, thus providing a model for crisis intervention by care-givers who can use the leverage of this common natural phenomenon for maximum preventive efforts in the population.

Increased community demand for psychiatric services. In the last 20 years, the increased role of psychiatry in the community has been encouraged by a greater public interest in mental health and more vocal demands for service. This was stimulated by books and films such as "The Snake Pit," and newspaper series revealing the inadequate and archaic conditions of many mental hospitals, such as *The Shame of the States* by Albert Deutsch. Public concern was, however, particularly aroused by the Second World War, when about 1,767,000 out of 4,800,000 men had been rejected for emotional or educational disorders and deficiencies. Forty per cent of medical discharges had been for psychiatric reasons; and in 1946, 60 per cent of cases hospitalized under the care of the Veterans Administration were psychiatric and cost the government about \$40,000 a case. In addition to such powerful reminders of the toll of mental illness, the

public after World War II was in an optimistic mood; so many advances had been made by science in the creation of comforts and in the conquest of disease that it was within the realm of possibility that insanity could be likewise overcome.

Citizen mental health efforts. Some of this public concern took a highly constructive form. Lay groups were created to alleviate certain mental disorders or to promote interest in their research, diagnosis, and cure. Among these have been Alcoholics Anonymous, Synanon, and various agencies to prevent suicide. Other groups included Golden Age Clubs and local citizens' mental health and mental hygiene associations concerned with the promotion and funding of research and services. Moreover, many community agencies, such as schools, churches, YMCAs, clubs, and other groups, have become more conscious of the mental health aspects of their own work. These have reached out for closer cooperation with and understanding of local psychiatric services.

One citizens' group, the Association of Parents of Retarded Children, can be singled out for special mention because of the importance of its impact on public opinion and its leverage on governmental action. Until 10 to 15 years ago there was a widespread attitude of shame and reticence among the families of retarded children, because it was believed that mental retardation was hereditary so that a defective child meant that the rest of the family was probably tainted. Then a number of studies began to be publicized which demonstrated that illnesses of the expectant mother such as German measles, or toxic conditions that interfered with the oxygen supply of the fetus, or birth trauma might damage the brain of the newborn baby and cause severe mental retardation. Parents of the severely retarded began to look on their problem as resulting from an unfortunate accident rather than a hereditary taint, and began in increasing numbers to band together and openly demand better services for their children. Since many of the exogenous causative factors of retardation are no respecters of social class, it turned out that many of these parents happened to be politically active and influential people, including even the family of the President of the United States. These people began to speak out publicly and to campaign actively for improved programs to prevent and remedy the ill effects of mental retardation, and these efforts helped swell the mounting public demand that local, state, and federal governments should assume responsibility for the organization of community services for the whole range of mental disabilities.

The success of such special interest groups has been facilitated by an increased public sophistication in health matters, particularly in regard to mental health. The latter is related to the widespread interest in psychoanalytic theories of behavior and interpersonal relationships among American intellectuals, especially writers, in the postwar period. The dissemination of their ideas to the general public has been helped by

the greatly increased communication power of the mass media, especially television, over the last 20 years.

Government support for community mental health. Lay concern has been reflected in legislative action on both state and federal levels, action which marked a logical continuation of New Deal and war-time assumptions of responsibility for public welfare. During the war, the federal government had encouraged and financed scientific and medical advances; after the end of hostilities, it seemed logical and necessary to many that the nation continue such patronage, particularly in areas such as mental disease which seemed remote from the great advances in other branches of medicine and which accounted for an enormous wastage of men and money. A federal government agency has existed for dealing with mental health matters ever since the Narcotic Division had been turned into the Division of Mental Hygiene in 1930.

The National Mental Health Act. In 1945, Robert Felix, the Director of this body, encouraged the introduction of a bill to Congress which became known as the National Mental Health Act. Passed in 1946, it provided for fostering and aiding research relating to causes, diagnosis, and treatment of neuropsychiatric disorders; it provided funds for the training of professional personnel; and it granted aid to states to establish clinic and treatment facilities and demonstration projects for the prevention, diagnosis, and treatment of mental disorder. In 1949, the Division of Mental Hygiene was abolished and was replaced by the National Institute of Mental Health. This 1946 bill was to have an enormous influence on the promotion of work in the mental health field. In 1946 \$2,500,000 was being spent throughout the country on research in psychiatry and allied fields. In fiscal 1965, the National Institute of Mental Health awarded \$86,331,000 for such research. The figures for training grants are equally impressive, \$4,250,000 in 1948 and \$81,643,000 in fiscal 1965. Associated with this has been a major increase in the numbers of mental health professionals, from about 4,000 psychiatrists in 1945, for example, to about 19,000 in 1965.

The Mental Health Study Act. Various "community mental health services" bills were passed in such states as New York, California, Minnesota, New Jersey, and Vermont to provide local programs for prevention, treatment, rehabilitation, and educational service facilities. In 1955, the Mental Health Study Act was passed whereby Congress directed the establishment of a Joint Commission on Mental Illness and Health in order to carry out a

... nationwide analysis and reevaluation of the human and economic problems of mental illness and of the resources, methods, and practices currently utilized in diagnosing, treating, caring for, and rehabilitating the mentally ill... [which] may lead to the development of comprehensive and realistic recommendations... and give promise of resulting in a marked reduction in the incidence or duration of mental illness, and in consequence, a lessening of the appalling emotional and financial

drain on the families of those afflicted or on the economic resources of the states and on the nation.

Report of the Joint Commission. A final report of this joint commission of leaders in psychiatry, psychology, social work, education, and the social sciences appeared in 1961. It followed studies carried out by the staff assembled by its director, Jack R. Ewalt, on theories of positive mental health and methodological problems of epidemiological research, the economics of mental illness, mental health manpower trends, community and research resources in mental health, the role of schools and churches, and current developments in the in-patient and out-patient care of the mentally ill. In contrast to the comprehensive programs outlined in state and federal legislation, the recommendations of these mental health professionals were largely restricted to the adult mentally ill. They also focused mainly on plans for improving the mental hospitals of the country through reducing their size, improving their resources, and extending their services into the community, in an effort to deal more effectively with acute and chronic psychotic patients, whose care was shown to be currently neglected. Their attitude toward prevention was that while they supported efforts in this field, they felt that the mental hygiene movement had diverted attention from the core issue of major mental disturbance. While they approved of the programs of public mental health education and of child and adult guidance clinics, they felt it necessary to redress the balance and to direct more effort toward secondary prevention, the early, and effective treatment of the mentally ill.

Legislative impact. The public and its government, however, still preferred to reaffirm the importance of comprehensive community programs. President Kennedy, in his message following the Joint Commission Report, wrote:

Central to a new mental health program is comprehensive community care. Merely pouring federal funds into a continuation of the outmoded type of institutional care which now prevails would make little difference. We need a new type of health facility, one which will return mental health care to the mainstream of American medicine, and at the same time upgrade mental health services.

In the part of his message devoted to mental retardation, he said: "Prevention should be given the highest priority in this effort." He advocated developments in the general health, education, welfare, and urban renewal fields which made it clear that he was focusing on primary prevention.

The Community Mental Health Centers Act. In 1963, Congress passed the Community Mental Health Centers Act which authorized the appropriation of \$150,000,000 to finance up to two thirds of the cost of constructing comprehensive community centers throughout the country, and an additional \$126,000,000 for research and treatment facilities for the mentally retarded.

During the period 1963-1965, \$8,400,000 of federal

funds were allocated to the states to finance the planning for the future community mental health centers. The guidelines allowed each state to develop a plan in line with its own special needs and resources but required the mobilization of state, local, private, and voluntary resources in the planning process; they called for a statewide inventory of existing facilities and a survey of local needs so that priorities could be established to govern the choice of sites for the new centers.

The regulations covering the 1963 act defined the centers in terms of programs rather than buildings, and it listed their essential elements. Each program, in order to qualify for federal funds, must accept responsibility for serving the needs for prevention, treatment, and rehabilitation of the total community, irrespective of age, sex, or class, residing within easy access of the center in a geographic area with a population between 75,000 and 200,000.

Implications for community mental health. This act and its regulations, as well as the federal stimulus to state planning, are likely to have a major effect on the evolving patterns of mental health service, research, and training programs throughout the country for years to come. What is still not clear is how the mental hospitals will be articulated with the community-based services. Certainly, continued care facilities must be available to local programs in order to satisfy the needs of a significant proportion of psychotic patients. In 1963, Congress appropriated 10 million dollars for intensive demonstration and pilot projects in mental hospitals to improve their quality of care and to provide in-service training for their personnel. The intent of this grant was to improve the mental hospitals so that eventually they could be integrated into the overall statewide plan. In Massachusetts the attempt is being made to use the state mental hospital as the community mental health center for its local district and also to use it as the continued care facility for several adjoining districts, each of which will have its own center which will provide short term care and general preventive and rehabilitative services.

One point emerges clearly from these recent developments, namely that the leaders of the country are committed to the new approach, advocated by President Kennedy, to foster the organization of comprehensive services for total populations and to coordinate them so that they serve the diverse needs of every resident. This is in contrast to the past pattern of providing institutions and services to which some of those people may secure admission who qualify because their identity or the nature of their disorder fits the appropriate admission category. This change of policy in the mental health field is in line with similar changes that are taking place in the fields of education, general health, and welfare. In this country, as in many of the democratic countries of Europe, federal and state governments are recognizing their responsibility to guarantee the fundamental right of every citizen to receive ade-

quate education, health, mental health, and welfare services. This implies a move from an institution or profession focus to a population focus, and this means a commitment of government to a community psychiatry point of view.

Historical roots. This development is related to a number of historical trends. Accelerating technological advances are reducing the need for manpower in the fields of agricultural and industrial production and thus freeing an increasing number of man-hours. The result is either unemployment due to redundancy or a shorter work life and increased leisure for the stably employed. The alternative is a major movement of workers from production of goods and food supplies to the provision of human services. The need to increase the proportion of workers providing educational and welfare services to others is complemented by the necessity and feasibility in our affluent society to expend federal funds at the local level in order to maintain the national economy. This has been facilitated during the past 10 to 15 years by an increasing relaxation of traditional tensions between federal and state governments, so that there is less fear that the federal government will infringe unduly upon states' rights if it enlarges its financial support of their programs in health, education, and welfare. During the same period there has been an acceleration in the growth and political power of the cities, which has opened up direct channels for the flow of federal funds to local service programs through newly created governmental departments such as the Office of Economic Opportunity and Housing and Urban Development. The net result of these changes has been a vast increase in federal spending for local programs in urban renewal, manpower development such as vocational training and rehabilitation, education, welfare, public health including medical care, and also mental health and mental retardation.

Current status of community mental health services. In all these fields the increasing funds and demands for program expansion have upset the preexisting patterns of organization of services and have overstrained the resources of professional manpower. Increasing dissatisfaction is being expressed with professional and agency boundaries and traditional practices. For instance, at the 1965 White House Conference on Health, the most frequently voiced criticism of the current situation was that increasing specialization and compartmentalization of health services have resulted in large segments of the population, especially the urban poor, being cut off from adequate medical care. The demand was made for attention to the provision of services to a total population, irrespective of race, color, creed, and class, rather than merely focusing on developing high level institutions or methods without regard to their availability to the public. Since the supply of health professionals was obviously not sufficient to satisfy the needs of the whole population, this led to the demand for recruitment and training of

large numbers of nonprofessional and subprofessional health workers, who would act as bridge agents between the specialists and the people.

Similar issues in allied fields are illustrated by the growing clamor for attention to school dropouts rather than catering only to students who fit into the demands of our school systems; the demand both in the Catholic and Episcopal church that clergymen go outside the walls of their churches and carry the word of God to the people in the cities; and the efforts of the legal profession to extend their services beyond the upper and middle classes to the poverty levels of the population. The welfare provisions of the "Great Society" are to be seen not only within the context of the interests of a particular president and party, but also as a manifestation of the evolving spirit of the times. The drive toward a community approach in psychiatry is merely one sign of this larger economic, social, and political movement. Other signs include civil rights and anti-poverty legislation, which have in part been a response to the militant agitation of social action groups composed of the racially and economically disadvantaged. It is becoming more common for civic leaders and planners to talk about the political and moral power of the poor and be less influenced by the vested interest groups of the professionals and the care-giving agencies—as evidenced by the recent passage of Medicare in spite of the staunch opposition of the medical lobbyists.

The future will show how these fundamental changes associated with both the demands of the people and the response of their elected leaders will be met by the professions which have developed their attitudes and theories and skills, and which have recruited and selected and trained their members, in line with the traditional categorical service approach.

The Characteristics of Community Psychiatry

Current thinking about community psychiatry emphasizes the following characteristics as its most significant features.

The concept of responsibility. Community psychiatry includes responsibility for prevention, treatment, and rehabilitation of mental disorders in a population which is defined either by membership in an institution or association, or by living in a locality:

1. The responsibility may be delegated by government, assigned by voluntary citizen or agency consensus, or assumed by the professional and his group.
2. The responsibility must extend beyond the known cases of mental disorder to the unrecognized cases of current or future disorder in the population. It must cover the entire population irrespective of age, class, or diagnostic category. It is circumscribed only by the arbitrary boundaries of what is defined as mental disorder or a mental health issue in that community.
3. The community psychiatrist operates with a continual awareness that he is one member of a group of community agents in fulfilling his responsibilities. (It

should be noted in this connection that in this section the terms "community psychiatrist" and "community mental health specialist," who may have a background in a variety of clinical, social science, or public health disciplines, are used interchangeably, as are the terms "community psychiatry" and "community mental health.") The group of community agents also includes members of the traditional mental health professions (psychologists, social workers, psychiatric and mental health nurses, occupational therapists, etc.), *plus* a new group of community-oriented professionals who have specialized contributions to make in this field, such as sociologists, anthropologists, political scientists, health educators, community organization specialists, lawyers, economists, epidemiologists, biostatisticians, *plus* the community care-giving agents such as doctors, lawyers, teachers, clergymen, policemen, public health nurses, *plus* the civic leaders and administrators, *plus* non-professionals, volunteers, and informal care-givers.

The community psychiatrist or other mental health specialist has a dual focus: on goals he achieves by direct action and on goals he achieves indirectly by the mediation of these other workers. Consultation, collaboration, coordination, and community organization are therefore central to community psychiatry.

Goals of community psychiatry. A major goal of community psychiatry consists of regularly monitoring the population in order to discover those people who are vulnerable to or suffering from mental disorder, and those situations and forces which are influential in this regard. An allied goal is that of discovering the wants of the population in regard to salient ills to be combated, and the translation of these feelings of need into practicable preventive and remedial programs.

Planning and administrative procedures. The community psychiatrist must be preoccupied with the planning process, which must define and set priorities on goals related to the felt needs of the population; which must work out ways of optimally achieving these in the most economic way possible within the limits of allotted resources of money, manpower, and knowledge; and which must evaluate results and give an account of these to those who assigned his responsibilities.

Since community psychiatry entails comprehensive programming which deals with complex biological, psychosocial, and sociocultural factors in people of all ages and classes, it usually involves mental health operations conducted by a number of different agencies and specialists which are likely to be administered under governmental, voluntary, and private auspices; and it invariably involves the collaboration of these with the whole network of community operations in such fields as health, welfare, education, religion, law, corrections, and the like. Political, community organization, and administrative knowledge and skills are, therefore, an integral aspect of the armamentarium of the community psychiatrist.

Research activities. Community psychiatry involves

not only practice skills covering all these activities. It also involves major research fields: (1) studies of population-wide forces which promote or inhibit increases in incidence and prevalence of mental disorders; (2) studies to develop methods and techniques of direct and indirect action to reduce community rates of disorder; (3) studies to identify and monitor changes in community rates of disorder; (4) studies to describe and specify program elements which are of preventive and remedial significance; (5) studies to evaluate the efficacy of programs, methods, and techniques; and (6) development of conceptual models and theories to form a set of guidelines for practice and for research, which in turn will modify them and foster progress in dealing with field problems and in professional education.

Similarities and Differences between Community Psychiatry and Clinical Psychiatry

Community psychiatry encompasses the diagnosis, treatment and rehabilitation of patients, and so it encompasses clinical psychiatry. A community psychiatrist must therefore be a competent clinician. His clinical interest in ameliorating the sufferings of individuals will help keep him aware of this fundamental target as the integrating thread of his manifold and complex community operations.

His clinical skills and posture provide an excellent platform upon which to base the acquisition of community skills such as mental health consultation, community organization, and administration.

The major differences derive from the contrast between his responsibility as a clinician for the welfare of his own patients with whom he has a contract for direct remedial action, and his responsibility as a community psychiatrist for the welfare of a population with most of whom he will have no personal contact.

Community psychiatry demands additional models and methods to supplement those of the clinician. It demands the ability to move easily from the clinical focus on a patient or family who are seen as unique individuals, to the community focus which sees the individual as representative of segments of a population and seeks to grasp the nature of the community-wide forces which impinge upon them.

Definition of Concepts and Terminology

During the period under review many terms have been used to denote all or part of the fields of practice and research associated with community aspects of the prevention, treatment, and rehabilitation of mental disorders. These have included community psychiatry, community mental health, public health psychiatry, public mental health, social psychiatry, preventive psychiatry, comprehensive community psychiatry, and mental hygiene.

Up to the present no common usage has emerged. Leaders in the field have used some of these terms interchangeably and have used others to delimit par-

ticular aspects of theory, practice, and research. Confusion has arisen because writers have used different terms for the same area and have used the same terms to denote areas with different boundaries. Because of this overlap in the meanings of terms in the field, it is necessary to define each term as it is used in a particular discussion in order to enhance meaningful communication. This complicated field can be delimited along various parameters. There are many possible ways of dividing it validly for descriptive and analytic purposes.

The following are its main parameters:

1. Is the focus primarily on individual patients (alone or with their families), or is it on populations (which include both sick and well)?
2. Which factors are regarded as most significant in the causation of mental disorder, and consequently receive major attention—social, psychological, or physical, or some combination of these?
3. Which factors are regarded as most important for prevention, treatment, or rehabilitation—social, psychological, or physical, or some combination of these?
4. Is the primary focus on correcting pathology, on preventing illness, or on promoting and maintaining health, or some combination of these?
5. If prevention is included, is the main focus on primary, secondary, or tertiary prevention, or all three?
6. Is the focus on service or on research, or both?
7. Is the location of the program inside institutions, such as mental hospitals or psychiatric clinics, or is it extramural, or both?
8. Are the auspices of the program governmental, voluntary community agency, private, or some combination of these?
9. What is the professional identity of the director and the workers of the program—i.e., are they psychiatrists, other clinicians, social scientists, other caregivers and administrators, civic leaders, etc., or some combination of these?

If each worker defines the program or conceptual field which is his focus along each of these parameters, the name he arbitrarily uses to denote his field will be readily understood by others, and eventually some agreement may be reached on a common terminology.

The usage at the Laboratory of Community Psychiatry of the Department of Psychiatry, Harvard Medical School, may be cited as one common way of categorizing and naming significant aspects of the field.

The term "*community psychiatry*" is used synonymously with "*comprehensive community psychiatry*" and "*community mental health*" to denote a focus on (1) populations; (2) all etiological factors, social, psychological, and physical; (3) all preventive, treatment, and rehabilitation factors, social, psychological, and physical; (4) correcting pathology, preventing illness, and promoting and maintaining positive mental

health; (5) all types of prevention; (6) both service and research; (7) both intramural and extramural; (8) auspices which include governmental, voluntary community agencies, and private jurisdictions; and (9) programs in which administrators and workers may be drawn from the ranks of social science, psychiatry, other clinical professions, and administration.

The term "*community psychiatry*" is used to denote the knowledge and skills needed by psychiatrists to encompass the above topics. The term "*community mental health*" is used to denote the knowledge and skills needed by a multidisciplinary group including psychiatrists, psychologists, social workers, nurses, social scientists, and the like, to encompass the same topics.

The term "*preventive psychiatry*" covers the same parameters, but with an orientation which emphasizes the public health approach of primary prevention (reducing the incidence of mental disorders and promoting positive mental health), secondary prevention (reducing the prevalence of mental disorders), and tertiary prevention (reducing the community rate of residual defect due to mental disorders). Since the three types of prevention cover the whole field of the organized community aspects of preventing, treating, and rehabilitating mental disorders in a population, "*preventive psychiatry*" is used interchangeably with "*community psychiatry*" and "*community mental health*." Each refers to the total field, the differences being those of emphasis or of audience. Thus, the title of the unit in Harvard Medical School is the Laboratory of Community Psychiatry to denote that its primary focus is to extend the knowledge and skills of psychiatrists as part of the Department of Psychiatry. The Laboratory's program of education for specialists who will exercise leadership in community services for the prevention and control of mental disorders and who will conduct research and educational programs in this field, is called the *Community Mental Health Training Program*. This signifies that both the faculty and the student body are composed of people from many disciplines, which include psychiatry, psychology, social work, nursing, social science, law, statistics, administration, and the public health professions.

The Laboratory does not follow the terminological usage of the various state legislative acts which restrict the term "*community mental health*" services to local programs such as out-patient clinics, psychiatric departments in general hospitals, rehabilitation services, and mental health education and consultation services, and which exclude the services provided in mental hospitals.

In this laboratory the term "*social psychiatry*" is used, although only occasionally, to denote the study of the social factors in the natural history of mental disorders as well as the sociocultural dimension (as contrasted with physical and psychological aspects) of preventive and remedial programs, such as the organization of therapeutic communities, milieu therapy,

community development, and social action programs, etc.

The term "*mental hygiene*" is no longer used because its meaning has nowadays become so imprecise. The term "*public health psychiatry*" or "*public health mental health*" is occasionally used to denote a program of service and research which is carried out under the auspices and within the administrative framework of an official public health agency, as contrasted with a community mental health program the auspices of which encompass not only governmental, but also voluntary or private jurisdictions.

The Roles of the Community Psychiatrist

Within the general framework of community psychiatry a variety of different full time positions are open to psychiatrists operating at federal, state, regional, county, and local levels in organized programs for the prevention and control of mental disorders in circumscribed populations, as well as in research and training. Part time positions in community psychiatry are also open to psychiatrists who may spend the remainder of their professional time on research or teaching in universities, in clinical practice in institutions, or in private practice.

Population focus. The psychiatrist who accepts a position in a program of community psychiatry must be prepared for a wide range of activities and responsibilities, which will involve his accepting a number of different roles. The population to which he ministers may be circumscribed geographically, that is, by residence, within certain boundaries, e.g., state, county, city, or neighborhood; or else functionally, that is, by membership in an organization, such as a college, a trade union, the Peace Corps, or an army unit; or in a particular group, such as low income families, unemployed workers, unmarried mothers, or the aged. However the boundaries of the population may be defined, the psychiatrist will be asked to accept some measure of responsibility for supervising the mental health of its total membership. This may include discovering and arranging clinical treatment for as many as possible of those who are judged mentally disordered; participating with other professional and nonprofessional community workers in helping those who deviate from social norms of behavior, such as delinquents, drug addicts, alcoholics, prostitutes, maladjusted or nonfunctional workers; collaborating with other workers in helping people cope with the crises of everyday life and thus aiding healthy personality development and preventing mentally unhealthy outcomes; and participating in community services for optimizing the level of adjustment and satisfaction of psychological needs of the population.

Professional responsibility: Level and nature. The level and nature of the psychiatrist's professional responsibility and accountability will vary according to which of these subpopulations he is dealing with. He will have the traditional medical responsibility for

his own patients, and in this area he will be given full control of the field, assisted by auxiliary personnel working under his direction. In other areas of the field such as handling deviants, he will be collaborating as an equal with other professionals such as lawyers, teachers, policemen, nurses, and general practitioners. In yet other areas, such as optimizing general levels of adjustment and need satisfaction, perhaps by improving living conditions through city planning or modifying the occupational or educational systems, he may be consulted by others to whom the main responsibility has been allocated, such as legislators, city planners, educators, and government officials; in those cases he plays a subsidiary role, which means that his contributions may or may not be used by the others in accordance with the trust and respect which he has earned for himself and with the perceived relevance of his suggestions for their plans.

The shifts from full responsibility and control to partial responsibility and equal status, and then on to a subordinate status as an advisor to others who carry the responsibility and the power, involve an emotional as well as an intellectual burden to a psychiatrist who has been trained for a circumscribed and homogeneous role pattern. Not all psychiatrists will be willing to learn how to make these role shifts, and some will wish to restrict their activities, as in the past, to traditional clinical practice, which will always be a necessary ingredient in any community plan for the control of mental disorders. More and more, however, community leaders are calling on psychiatrists, as well as on other professionals, such as lawyers, educators, and clergymen, to widen their area of professional operations in order to play a part in concerted solutions for community-wide problems.

Many psychiatrists will rise to this challenge and will add to their traditional skills of diagnosis, prognosis, disposition, therapy, management, and rehabilitation of patients, a range of community-oriented skills such as community organization, planning, collaboration, mental health consultation, mental health education, and community development. The goals of the psychiatrist in this community work are to play an active partnership role in collaborating with certain members of other professions in jointly planned and organized projects and also to place his specialized knowledge and understanding of mental health matters at the disposal of other professionals and administrators, so that they may improve their handling of the mental health dimension of their own tasks.

personnel involved. Typically, the professional activities of the public health psychiatrist include extensive interaction with a wide variety of governmental structures and agencies at federal, state, and local levels; liaison with diverse lay and professional organizations; and, to a limited degree, contact with the mass media. These activities may be political, administrative, and financial in nature.

In this section, the community problems which mold the definition of mental health will be discussed from this perspective. A selected set of activities will then be described to illustrate the current approach to these problems in the field of mental health and related planning.

Definition of Mental Health: General Considerations

The difficulties inherent in defining mental health are too well known to require documentation. By its very ambiguity this "definition dilemma" serves as a platform for those propounding a human ecology which encompasses at least the earth, if not the universe, to those in search of the elusive, subatomic cause of psychological ills.

The clinician often defines mental health as resistance to, or absence of, mental illness. Thus, Ewalt and Farnsworth approached the definition problem as follows: "As we see it, the individuals who have basic confidence in themselves and others, a sense of competence, and a feeling that the whole human situation is meaningful and worthwhile, have a great deal more resistance to emotional decompensation than do those who have attitudes and feelings causing insecurity."

Levinson et al. adopted a more ecologically oriented approach in their investigation of the many social and environmental factors which promoted or inhibited mental health in a group of employees of a large utility company. Mental health was considered to depend primarily on the way the individual felt about himself, other people, and the world, particularly in reference to his own place in it. Within this context, special significance was attached to his feelings about earning a living and his responsibilities toward those who depend on him.

One of the best known definitions of mental health even includes the element of happiness. As stated by Karl Menninger in 1947, "Let us define mental health as the adjustment of human beings to the world and to each other with a maximum of effectiveness and happiness. Not just efficiency, or just contentment—or the grace of obeying the rules of the game cheerfully. It is all of these together, socially considerate behavior, and a happy disposition. This, I think, is a healthy mind."

Ginsburg's definition of mental health, in terms of its relationship to environmental mastery, as manifested in three crucial areas of living—love, work,

45.2 DEFINITION OF MENTAL HEALTH AND DISEASE

BERTRAM S. BROWN, M.D.

Public health psychiatry has been variously labeled community, social, or administrative psychiatry. This author, in a less serious vein, has used the term "political psychiatry" on occasion, simply to highlight an oft neglected aspect of this work. Similar variations in theoretical orientation are apparent in definitions and discussions of these newly emerging chameleon concepts. Until these issues are resolved, perhaps clarification and classification in this field of psychiatry had best follow, in some measure, actual description of the variety of problems, concerns, and issues which engage the energies and intellects of the professional

and play—is particularly useful: “My co-workers and I have settled for some simple criteria as these: the ability to hold a job, have a family, keep out of trouble with the law, and enjoy the usual opportunities for pleasure.”

As Jahoda pointed out, the polarity of mental health versus mental illness has been used frequently and persistently as the basis for simple definitions of mental health. Clearly, however, a full description of the meaning of the term “mental health” cannot be provided within this framework. In fact, the situation is exceedingly complex even from the limited purview of this polarity. Are we concerned with the sick and/or the well? Can we identify the “pre-sick” among the well? Is the oft stated concept that as psychiatrists—and physicians—our first responsibility is to “major mental illness,” rather than preventive work, a valid one? Do we, in fact, know enough about prevention to focus on this area?

These questions are not unique to public health psychiatry, nor are they encountered more frequently there. However, in other areas of specialization, they take the form of clinical dilemmas, for the most part, which center around an individual patient. In contrast, in public health psychiatry, they emerge as administrative and political issues which are often colored by conflict over control and supervision of finances for program purposes, rather than theoretical and therapeutic considerations. This is best illustrated by a group of problems which, it is generally agreed, are closely related to mental health (although the closeness of this relationship remains controversial). These “pressure,” or problem areas include alcoholism and drug abuse, mental retardation, crime and delinquency, and aging. Are they blood brothers, or distant cousins? The feuds, some fertile and others futile, which characterize the relationships between these so-called pressure areas and community mental health efforts clearly reflect the administrative adolescence of public health psychiatry. More specifically, they point up the crucial need for establishment of a social and organizational identity.

Mental Illness versus Mental Health

The brief discussion of these problem areas presented below is designed to highlight key issues and controversies. Hopefully, it will also serve to clarify the nature of the substantive problem areas and, in so doing, clarify the problem inherent in the definition of mental health.

Alcoholism. Alcoholism is a multifaceted problem which has evoked the interest of diverse disciplines, ranging from anthropology to zoology. The relationship of alcoholism to mental health is equally diverse. Clinically, it is seen as an effect and/or cause of mental disorder or emotional problems. Administratively, at the state level, alcoholism programs may be either independent of or under the aegis of a mental health agency. Programmatically, alcoholics may be

specifically forbidden or actively encouraged to utilize a variety of mental health services, such as general hospitals, in-patient psychiatric services, and out-patient psychiatric clinics. Legally, the alcoholic may be considered mentally disabled and, like the psychotic and mentally retarded, not responsible for his criminal behavior. Or, on the other hand, he may be subject to special laws, governing such matters as commitment and treatment.

Some social forces, manifested in part through national voluntary organizations, actively discourage direct identification of alcoholism with mental health sponsorship or leadership. The reasons given by these organizations for their aversion to such an affiliation range from the desire for autonomy and visibility for purposes of program growth and fund raising, to the conviction that alcoholism is *not* a mental health problem. Rather, the alcoholic's problem is simply that he “drinks,” that he lacks will power or religious conviction, and so forth.

Mental retardation. President Kennedy's historic message to Congress on “Mental Illness and Mental Retardation” begins with a brief introductory section which addresses itself to the common concerns of mental illness and mental retardation, followed by two distinct sections: “I. A National Program for Mental Health,” and “II. A National Program to Combat Mental Retardation.” Clearly, this orientation provided impetus for the formal expression of the separatist view of mental illness and mental retardation. In fact, however, the historic roots of this schism run deep, reflecting long decades of neglect of mental retardation by psychiatry. This neglect becomes particularly apparent when it is contrasted with the recent success in effective program development in mental retardation due primarily to the active efforts of lay organizations. In any event, the complexity of the current relationship between mental health and mental retardation is evident at many levels.

At the federal level, administrative responsibility for various aspects of mental retardation resides in several of the constituent agencies of the Department of Health, Education, and Welfare. In contrast, mental health responsibility is, for the most part, centralized in the National Institute of Mental Health.

There is considerable variation in the administration of mental retardation programs at the state level. In some instances, departments of mental health bear the major responsibility for mental retardation programs. Other states maintain separate mental health and mental retardation departments. Again, there are variations in local programs which may discriminate for or against services to the mentally retarded. In general, however, even in programs designed specifically for the retarded, such as child-centered diagnostic clinics, a significant proportion of the patient population is not retarded but manifests emotional or psychological problems.

At the clinical and conceptual level, the question of whether mental retardation can ever exist without concomitant emotional problems is a continued source of controversy. There is no question, however, that mental retardation represents a significant mental health problem for the family.

Finally, perhaps the overlap between these areas is demonstrated most clearly by the fact that the same personnel—psychiatrists, psychologists, social workers, and educators—are involved in the diagnosis and management of both problems.

The underlying issues inherent in the definition of mental health vis-à-vis mental retardation are similar to those discussed above with regard to alcoholism. In brief, professional and lay groups which have organized independent mental retardation programs object to mental health sponsorship on the grounds that the problems of mental illness (health) are different in certain essential respects from those associated with mental retardation, and/or because of their desire to preserve the critical aspects of visibility, autonomy, and the growth potential of their own programs.

Other pressure areas. An analogous situation pertains in the field of crime. That is, the conviction held by many law enforcement officers, laymen, and even some psychiatrists that most criminals are not mentally ill, and that crime is not a mental health problem clearly precludes a close relationship between this pressure area and mental health.

With the passage of "Medicare" (Public Law 89-97) and the Older Americans Act of 1965 (Public Law 89-73), the proper function of mental health in the field of aging has been subjected to intensive examination. Are psychiatrists more appropriately concerned with the aged mentally ill, or the mental health aspects of aging? The obvious answer is that their concern encompasses both facets of this problem. But in this field, as in the others described previously, whenever the mental health specialist leaves the shelter of the treatment setting and indicates a desire to step out of his traditional role as healer of the mentally ill (i.e., in cases where the presence of mental illness is clearly established), he emerges into an arena of conflicting and competing interest groups.

Briefly summarized, the battle between mental illness and mental health subsumes two major campaigns. One might be likened to an air battle; it involves a conceptual struggle over differences in approach to social problems. The other is more like traditional ground warfare; the mental health agency represents only one of many interest groups involved in the struggle for power and authority. Inasmuch as they all have ethical goals for the use of this power—to benefit the aging, alcoholic, addict, delinquent, or retarded—at times various groups may well find ways to cooperate in order to help the population, which is the target of their common concern. But

even under such optimal conditions, autonomy will remain a source of disagreement. Furthermore, inasmuch as these various groups are concerned primarily with hierarchical position and jurisdictional power, these battles are surprisingly intense and chronic. Accordingly, they must be taken into account by those concerned with the development of comprehensive mental health programs. In addition, issues of administrative leadership and control play a significant role in molding the work environment of practicing clinicians.

Mental Health and Related Planning

It has been said that we have moved from the age of anxiety to the age of planning. Today, mental health planning is big business. It is, moreover, a rapidly changing, highly complex business.

In 1963 and 1964 Congress appropriated a total of \$8.4 million to support state-wide interagency comprehensive mental health planning. This planning effort has involved all the states, and almost every community in the nation, and required the active participation of more than 25,000 citizens, both lay and professional. The final reports of this planning effort became available in the fall of 1965. There is no question, however, that these reports will continue to have a major impact on the shape of psychiatric practice for the years to come, and will continue to be the subject of a great deal of study and controversy. It is significant, too, that the end of federal support for comprehensive planning in 1965 did not mark the end of formal mental health planning efforts in the majority of states. Many are continuing to maintain some form of mental health planning unit in the state mental health agency. Thus, at the very least, this total effort has spawned a new specialist in the field—the mental health planner.

The impact of mental health planning on planning in related areas. A question arises as to the relationship of this national mental health planning effort to planning in the fields of alcoholism, mental retardation, crime and delinquency, and aging. The answer represents a veritable kaleidoscope and is not easily summarized. At the state level, the principal mental health planning bodies included newly created governors' commissions and advisory groups, agencies which were given the responsibility for the new mental health planning, and private planning entities contracted for by state agencies. These various government and quasi-government groups varied greatly, not only in their formal responsibility for alcoholism, corrections, and mental retardation, but also in the manner in which they handled this responsibility.

All the planning efforts made some provision for special studies in problem areas. An analysis of the anatomy and taxonomy of this effort, based on a study of the composition of the task forces set up, reveals the underlying dynamics inherent in such a

process. For example, in many states, task forces addressed themselves to the general problems of aging or adolescence. In others, the task force limited itself specifically to the elderly mentally ill or the emotionally disturbed child. Similarly, in some states, task forces were directly concerned with all aspects of mental retardation; others were interested only in the mental health aspects of mental retardation.

The related planning efforts specifically addressed to the other fields further complicated this phenomenon of the widely fluctuating boundaries of the formal mental health planning effort. For example, under Public Law 88-156, "Maternal and Child Health and Mental Retardation Planning Amendments of 1963," comprehensive state-wide mental retardation planning was supported under a separate program.

Efforts in comprehensive mental health and mental retardation planning provided the backdrop for specific state construction plans, required by Public Law 88-164, "Mental Retardation Facilities and Community Mental Health Centers Construction Act of 1963." In fact, this legislation institutionalized the dichotomy; it consists of two separate parts, dealing with mental retardation facilities and community mental health centers, respectively.

To return to mental health planning per se, in relationship to community mental health centers, the broad range of planning envisioned is best indicated in the regulations for Title II of Public Law 88-164:

Section 54.203 State plan; elements of adequate services; facilities; relationship to other planning.

...
(d) Planning. The State plan shall show that:

- (1) It is consistent with the comprehensive mental health planning of the State;
- (2) Cognizance has been taken of other health planning efforts and planning in such areas as urban development, welfare services and related facilities;
- (3) In the case of interstate metropolitan areas, there has been consultation with the other State or States concerned; and
- (4) To the maximum extent practicable, there has been coordination with city, metropolitan area and interstate planning agencies to achieve consistency between the State plan for, and the delineation of areas to be served by, community mental health facilities and other health, welfare, and physical development plans and activities.

To further complicate matters, under the recently enacted amendments to Public Law 88-164 (P.L. 89-105), which provide federal support for the staffing of mental health centers, each state must also submit a new plan as an amendment to the state plan for mental health services under Title III of the Public Health Service Act.

Further delineation of these various plans and their requirements can serve no useful purpose. Clearly, we are dealing with a matter of some complexity. And hidden underneath this complexity, with its plethora of administrative and legislative issues, we find the difficulties inherent in the formulation of a proper definition of mental health. But when we view

the definition of mental health from the perspective of planning, the image assumes a more composite shape. In both instances, the pressures leading to the diverse picture include the political and administrative realities of disbursing and controlling large sums of money. They may also be attributed to intellectual and conceptual differences in regard to the proper domain of mental health.

In conclusion, the definition and boundaries of mental health await precise delineation. The rapid evolution of the field of community mental health has the quality of a social movement which is characterized by continuously expanding concerns. This is clearly apparent in the difficulty in understanding the relationship of mental health to mental illness, and of mental health to related fields, such as alcoholism and mental retardation. However, what is not evident to many practitioners is the fact that the events which shape the boundaries of legitimate professional concern are forged as clearly in the legislative, financial, and administrative arena as they are in the academic setting and the scientific laboratory.

These are the personal opinions of the author and do not represent formal policy of the National Institute of Mental Health.

45.3 MENTAL HEALTH AND SOCIAL FACTORS

DOROTHEA C. LEIGHTON, M.D.

ALEXANDER H. LEIGHTON, M.D.

Population studies and investigations of the socio-cultural variables influencing mental health are a development of the 20th century, more particularly of the period since World War I. Additional impetus developed during and after World War II from the high rejection rates of selectees for psychiatric reasons and from the number of medical discharges after induction due to development of nervous and emotional disorders. Psychiatrists and others became concerned to learn more about the proportion of unrecognized psychiatric disturbance in the supposedly normal and healthy population.

As understanding of the dynamics of psychiatric disorder has increased, there has been a marked growth of interest in determining what sectors of a population show the most disorder, which members of the sector are chiefly affected, and what correlates can be seen with characteristic sociocultural features. The earlier limitation of concern to those individuals who have obvious and impairing disorder has been replaced by an interest in discovering the total prevalence of psychiatric disorder of all degrees, from the very mild to the full blown. This parallels the kind of epidemiological development seen in studies of infectious diseases such as polio and tuberculosis. At first, only advanced stages were recognized, but eventually, in the case of tuberculosis, slight x-ray evidence or a mildly positive tuberculin skin test came to be taken as possible indication of involvement.

Population Studies

This type of epidemiological investigation had its beginnings in various studies of hospitalized patients who were examined for their geographic and social origins, seeking clues to significant relationships. A trail-blazing example is the work of Faris and Dunham, who determined the residential location of schizophrenic patients within Chicago and found a

concentration in the low class, central rooming house section of the city. More recently, Clausen and Kohn have examined the sociological characteristics of schizophrenic patients from a small city—Hagerstown, Maryland—where no such relationship could be demonstrated. They suggest that the lack of relationship may be a function of the size of the city, and they point out that similar studies by other people in cities smaller than Chicago but larger than Hagerstown show intermediate levels of correlation.

Another general scheme has been to take a geographic area, determine how many people show recognizable psychiatric disorder by the criterion of treatment or the opinions of key informants, and then relate type of illness to age, sex, socioeconomic status, ethnic origin, and so on. Well known studies of this type have been made by Luton and Roth in Tennessee, Hollingshead and Redlich in New Haven, Lemkau et al. in Baltimore, Jaco in Texas, and Eaton and Weil among the Hutterites. There have also been a number of such investigations carried out in northern Europe: Strömgren and Fremming on Bornholm Island, Brugger in Germany, Bremer in Norway, Kaila in Finland, Primrose in England, Sjögren in Sweden, and Helgason in Iceland. All these studies have increased knowledge of the relation between the occurrence of clinical psychiatric disorder and various conditions of life, as have others from other parts of the world, such as Lin in Formosa, Tsugawa et al. and Uchimara et al. in Japan.

Still another approach has been to estimate by some means the number of people in a defined group—a community, a county, a section of a metropolis—who show any degree of psychiatric disorder, regardless of whether they are being treated or have been previously diagnosed. This approach necessitates some kind of direct contact with at least a sample of the group under investigation; it has been carried out in two principal ways: assessment by psychiatric interview (Essen-Möller and Hagnell in Sweden) and collection of questionnaire data that were then assessed by psychiatrists (Rennie, Leighton, Gillis). When a questionnaire is used, data on many aspects of the subjects' life patterns are gathered, along with information regarding mental health status. Psychiatric questions in the survey are derived in part from screening instruments used by the armed forces before and during World War II.

Findings regarding the psychiatric status from these various types of study are expressed in a number of forms, such as rate (number of cases per unit of population); percentage of given diagnostic entities within the group examined; expected percentage of a condition within a particular sex, age, or social group; risk. Most studies have reported the *prevalence* of psychiatric disorder at a point in time or during a short period; a few have calculated the *incidence* of new cases per year or per 10 years, e.g., from data gathered at two different times.

Problems in evaluation. There are a number of problems connected with drawing conclusions from all these studies, especially in regard to determining prevalence and relationships with various sociocultural features between different population groups. Nearly every study has used a somewhat different method from every other one—working from records, informant data, or direct contact with subjects; investigators who are psychiatrists without much social science training, contrasted to investigators who are social scientists but not trained to judge the psychiatric data; variable definitions of what shall be counted as psychiatric disorder; use of local systems of diagnostic classification; different standards for social and other kinds of stratification. The list of problems is long and has been subjected to critical scrutiny by Dohrenwend and others.

If one regards most of the earlier investigations as pilot ventures that serve a useful purpose in delineating the problems and the later investigations as making many improvements but still not providing the final word, one can gain from this material some insight regarding avenues for future research. Even with imperfect methods and concepts, each new study of the interrelationships between social and psychiatric features suggests new meanings in the interactions. Recent efforts to follow a group of subjects over time, either by repeated surveys at intervals (New Haven, Sweden, and Stirling County) or by keeping in continuous contact (Washington Heights), promise to tell much about the natural history of psychiatric disorder that at present is only conjectural.

As illustration of both the problems and the potentials of population studies, there follows a brief description and comparison of three rather different yet philosophically similar studies: that of Essen-Möller in Sweden; of Srole et al. in Manhattan; and of Leighton et al. in Stirling County.

The Swedish study. This study, carried out from the University of Lund, represents the most nearly clinical method of the three investigations to be described. Essen-Möller and three fellow psychiatrists, all with very similar training, personally interviewed at home all the inhabitants of two rural Swedish parishes. They conceived their work as a medical census that would serve as a "background against which to judge the composition of a clientele of patients." They were especially interested in collecting evidence regarding the theories of natural and pathological variations in personality advanced by their teacher, Sjöbring, and the relationship of such variations to psychiatric disorder. They also wished to determine the demographic distribution of both the personality traits and the psychiatric disorder.

Before starting the interviewing, the four participants agreed on the topics to be covered and the means of doing so. Comparison of experiences after a week's work brought about some modifications and standardizations. In the end, there persisted certain

differences in emphasis between investigators, but "the descriptions and diagnoses turned out encouragingly homogeneous."

Free history taking was preferred in order to get a gestalt view of the individual. No tests or physical examinations were used. At the start simple questions as to health, sleep, and capacity for work were asked, followed by general inquiry into previous illnesses, doctors' calls, admissions to hospital, operations, periods of weakness, and nervous symptoms. Next came a discussion of health at different periods of life. Finally, schooling, training, jobs, and use of leisure time were discussed. Notes were made throughout on prepared sheets. Following this part of the interview came 30 specific health questions that were asked unless the information had already been obtained.

When the interviewing was completed, the information provided by the respondents was checked against hospital and doctors' records. The name lists were compared to the records of four mental hospitals; and parish records, alcoholic registers, economic official data, and school marks were systematically searched. In addition, a number of informants knowledgeable about the community scanned the name lists and provided comments on persons they knew. All these data were collated and codified and eventually put on punch cards.

The sample of 2,550 men, women, and children, from an area of 45 square kilometers, showed an age, sex, and marital status distribution very similar to what had been found by a recent census for the whole rural province.

During analysis, much attention was paid to the Sjöbring personality variants—capacity, stability, solidity, and validity—but these will not be discussed here, since such variables were not used in the other two studies with the exception of capacity, which includes mental deficiency. Each variant was scored for each subject according to judgments made at the time of the interview.

Material from the interviews was first classified as (1) subjective complaints (sleep disturbance, swooning, vertigo and dizziness, headaches, stuttering, tics and enuresis), (2) autonomic instability (migraine, vasomotor lability and acute psychosomatic reactions, spells and fits, climacteric complaints, sensations other than climacteric), or (3) mental complaints (fatigue, weariness, downheartedness, nervousness, sensitiveness, huntedness, susceptibility to hurry or to adversity).

The next step in analysis was to prepare some sort of integrative clinical diagnosis for each individual, using information from all sources, in the same way as a psychiatrist would do for a patient, and expressing findings in current European psychiatric diagnostic terminology.

The first diagnostic category was asthenic states, characterized mainly by fatigue and nervousness.

Cases of this type were divided further into subcategories of severity, depending on intensity of complaints and signs visible at interview, and also into subcategories of earliness according to whether the condition began before or after the age of 20.

The second diagnostic category comprised personal deviations, which were counted as minor if they would be recognized only by experts or as major if noticeable to lay persons. Subgroups in this category were typed as (1) aggressive, irritable; (2) restless; (3) indolent; or (4) cranks. Two other varieties were also differentiated: schizoid personality and ixoid personality. The first of these was loosely defined much as it is in North American psychiatry; the second was noted as being "sticky," "adhesive," and "accumulating." These last two types and the preceding four were not mutually exclusive—that is, a person could be noted both as schizoid and as aggressive-irritable.

Mental disease was limited to the third and fourth diagnostic categories, neurosis and psychosis, which were distinguished roughly according to intensity, so that neurosis was chiefly a mild disease and psychosis a more severe one. Neurosis had three subclassifications: (1) emotional lability, (2) anxiety states, and

(3) mild depressions. Psychosis subsumed (1) depressive psychosis, (2) manic, dysphoric, and confusional psychoses, and (3) schizophrenia.

A fifth category was intellectual deterioration, associated in most cases with some organic cause, such as senility, trauma, or chronic alcoholism. Remaining diagnostic categories were oligophrenia (severe mental deficiency) and alcoholism and asociality.

In addition to completing the interview, each psychiatrist noted at the end whether he considered the person, from a psychiatric point of view, as a pathological or abnormal variant.

Four classes were used, *evident* meaning that the individual's mental state would have been considered by most psychiatrists except perhaps analysts as due to pathologic interference; *probable* meaning that the condition was judged likely to be pathologic in the somewhat wider sense of Sjöbring psychiatry; *conceivable* meaning that even to this school, a diagnosis of abnormality was not likely but could perhaps not be discarded; and *no* pathology standing for individuals without any suggestion hereof.

In summary, the Swedish study was a clinical psychiatric investigation of a "normal" population. The method for data collection was a moderately standardized form of the usual clinical interview plus collateral material from medical and lay informants and from hospital and other records. Classification by diagnostic entities and by Sjöbring's personality variants, with correlations between these two, was the principal analytic procedure. Considerable social and physical data were gathered, and although distributions of the population by these factors were given, little was made of their correlations with psychiatric findings. Such relationships were an interest but not a main concern. All findings were given by sex and by age, the limits of the latter extending from birth to 92 years. Tables I and II show selected over-all findings but do not do justice to the painstaking statistical work of the monograph.

The Midtown Manhattan study. This study (Srole et al.) of a sample of 1,660 adults drawn from a section of New York City of approximately 175,000 population—110,000 adults aged 20 to 59—represents the greatest departure from usual clinical procedure of the three studies, as the Swedish study represents the least. It was directed by the late Thomas A. C. Rennie, a psychiatrist who made extensive use of the advice and assistance of social scientists of a variety of disciplines in the planning and execution of the research.

One of the participating psychiatrists, Michael, wrote:

In broadest outline the goals of this study were the estimate of the mental health of a community population, most of whom had never been psychiatric patients, and the study of the relatedness of mental health to a variety of demographic indices and to personal and social experience. Since mental health was the central theme, considerable effort was expended to achieve reasonable reliability and objectivity in the estimate of the mental health of each respondent. Information for the Mental

Health Rating was obtained through a questionnaire guided interview [conducted by a large number of nonpsychiatrist interviewers]. . . . A series of items derived from previously developed questionnaires designed for preliminary screening of mental disorder, such as the Cornell Medical Index, the Army Neuropsychiatric Screening Adjunct, and the Minnesota Multiphasic Personality Inventory were selected as the 'symptom core' of our questionnaire. Questions and probes used by psychiatrists in psychiatric examinations of clinical patients were also incorporated. Thus a broad cross-section of information was assembled from which conclusions might be reached on the presence or absence of psychiatrically significant symptoms.

A number of questions dealt with facts, such as age, sex, marital status, education, employment, income, religion, hospitalizations for somatic or mental illnesses, contacts with social agencies and activities related to recreation and pleasure. Other items probed for perceptions and attitudes of the respondents. . . . The rating psychiatrists had to be ever aware of possible misrepresentations introduced by the mental mechanisms of the respondents, and, when indicated, consider them in the evaluation of the Mental Health Rating.

The psychiatrists made essentially four psychiatric judgments on each respondent. Two of these described an overall rating of mental health on a graded continuum from health to illness. A third classified the respondent's personality and his symptoms with a clinical framework of modified diagnostic concepts, and a fourth estimated some of the respondent's symptoms.

The data used for these ratings were extracts from the full questionnaire. Part I of the extracts contained only symptomatic material and was the basis for the first mental health rating. Part II contained information pertaining to the subject's social functioning and, combined with Part I, formed the basis for the second mental health rating. Part II also contained, in some cases, information obtained from the social service files, such as records of hospitalization, court appearance, social service assistance, and application to welfare agencies.

The two mental health ratings—in fact, all the psychiatrists' judgments—were made independently and later compared and combined according to a regular procedure. The four final levels were as follows:

1. Well: no evidence of symptom formation
2. Mild: mild symptom formation but functioning adequately
3. Moderate: moderate symptom formation with no apparent interference with life adjustment
4. Impaired:
 - a. Marked: moderate symptom formation with some interference in life adjustment
 - b. Severe: serious symptom formation, yet functioning with some difficulty
 - c. Incapacitated: serious symptom formation, functioning with great difficulty, or unable to function.

These mental health ratings form the principal psychiatric referent for correlation with sociocultural factors in *Mental Health in the Metropolis*.

Diagnostic and symptomatic ratings, the third and fourth judgments required of the psychiatrists, were not nearly so central a concern of the research as was the mental health rating. The psychiatrists felt at a serious disadvantage here because they never saw the respondents and so could not subject them to the

familiar clinical examinations on which diagnosis rests. However, they were supplied with lists of a limited number of diagnostic groupings on which they checked an estimate of the prevailing personality structure and the character of the symptoms for each respondent, prefixing the diagnostic term with "probable" and suffixing it with "type" to indicate the tentative and limited nature of the judgment. The gross diagnostic types used were: (1) probable organic type, (2) probable psychotic type, (3) probable neurotic type, (4) probable psychosomatic type, (5) probable personality trait type.

The symptoms and symptom complexes listed for checking were: (1) epileptic, (2) intellectually retarded, (3) structural brain disease and/or senility, (4) alcoholic/probable alcoholic, (5) sexual deviant, (6) behavioral problem, dyssocial, (7) mixed anxiety, (8) anxiety, free floating, (9) anxiety, phobias, (10) obsessive-compulsive trends, (11) somatic preoccupied, hypochondriasis, (12) neurasthenia, (13) passive-dependent personality, (14) depression, (15) rigid personality, (16) schizoid personality, withdrawn, (17) aggressive personality, (18) suspicious, hostile personality, (19) schizophrenic, (20) cycloid-affective psychosis.

The combined mental health ratings were studied for their relationship to age, sex, marital status, own socioeconomic status (SES), rural-urban background, own religion, parental SES, generation in United States, religious origin, and ethnic origin. Most striking relationships were with age and aspects of SES. There was an increase in poor mental health with age by decades, the 50- to 59-year group showing 15 per cent well and 31 per cent impaired, as compared with 24 per cent well and 15 per cent impaired in the 20 to 29 group. Age limits were from 20 to 59 years.

SES was calculated from occupation, education, income, and rent. The highest stratum showed about six times as many members in the well group and less than a quarter as many in the impaired group as did the lowest stratum. When the other sociocultural factors were controlled for age and for SES, none of them showed significant correlations with mental health ratings (Tables III and IV).

The Stirling County study. This study is in several respects intermediate between the Swedish and the Midtown studies; it is less clinical than the Swedish study but more clinical than the Midtown study; a questionnaire interview was the basis of psychiatric assessment, as in the Midtown study; additional information from local sources was gathered, as in Sweden; much attention was paid to discrimination and classification of psychiatric reactions, as in Sweden; much attention was given to sociocultural considerations, as in Midtown; and the research was planned and carried out by a multidisciplinary team.

The principal idea behind the Stirling County

study was that, although individuals are limited by constitutional and biological factors, the way in which their capacities are developed or frustrated is to a large extent determined by the social environment in which they live. It follows from this that psychiatric disorder, like other behavior, is a reaction or adaptation to the environment, limited by constitutional and biological determinants. Thus, from its inception, the study was as much concerned with environment, especially social environment, as with psychiatric disorder. The aim was to try to determine which aspects of the environment were importantly associated with increasing psychiatric disorder. A leading hypothesis bearing on this was that a social environment that adequately fulfilled its incumbents' needs (integrated) would be associated with less psychiatric disorder than an environment that did not (disintegrated).

Stirling County provided a suitable area to investigate these relationships. Like the Swedish parishes, it is a rural area, but, since the researchers took the whole of a county, the extent and variety was considerably increased as compared with the Swedish study. The population of approximately 20,000, half French-speaking and half English-speaking, is scattered in small villages of a few hundred for the most part, with one town of 3,000 and a good many iso-

lated farms. The villages offered contrast not only in ethnic composition but also in sociocultural integration and disintegration, yet each village was small enough to make it possible for investigators to comprehend personal interactions, both intrafamilial and extrafamilial. The town of 3,000, in spite of its small size, presented a number of urban features, at least as compared with the smaller villages.

One of the first research moves was to make a selection of extreme examples of socioculturally integrated and disintegrated communities by consulting local key informants. Then social scientists lived in each of the five selected focus communities to study at close range the various features mentioned above. As the other major source of data, a sample of 1,010 adults was drawn from the county, with heavier sampling in the focus communities. This sample was interviewed with a questionnaire designed to elicit information that would make it possible to place each individual with respect to a number of sociocultural factors, with particular emphasis on the indicators of integration and disintegration, and with respect to the presence or absence of psychiatric disorder. For the latter purpose, a section contained an inquiry about health history and a series of neuropsychiatric screening questions rather like those used in the Midtown study, and from similar sources. The screening questions had been tested in advance on a population very similar to that of Stirling County.

As in Midtown, the questionnaires were administered by nonpsychiatrist interviewers. Many additional data were gathered, however, both for psychiatric and for sociocultural purposes. For example, all the local physicians were interviewed by the project psychiatrists for comments on any respondents they knew, and a search of hospital records was conducted in the local hospitals and in the mental and general hospitals at the nearest metropolitan center. The social science team interviewed key informants extensively throughout the county and learned much from participant observation in the selected communities. Further, in order to achieve greater depth of understanding of the psychiatric manifestations of the county, an out-patient psychiatric clinic was established in the principal town.

As soon as the collection of psychiatric data was completed, the psychiatrists turned their attention to developing a standard method of evaluating the mental health status of the individuals interviewed. For symptomatic terminology, the 1952 *Diagnostic and Statistical Manual of the American Psychiatric Association* (A.P.A.) was chosen because it was a recent attempt at an improved system of classification of mental disorders, it was familiar, and it furnished a series of definitions of the diagnostic terms. With some modification necessitated by using it on nonpatients in the survey, it proved workable. No attempt was made to decide on a single diagnosis for any respondent; rather, the A.P.A. *Manual* terms

were used to describe symptoms and symptom patterns that were evident in the material being evaluated, and as many as were appropriate were listed for each person.

In addition to assignment of these descriptive terms, two other judgments were made for each individual. One was a rating on a four-point scale that is strongly reminiscent of the scales used in both the Swedish and the Midtown studies. In the Stirling scale, the points expressed the degree of certainty felt by the evaluators that the person did or did not show psychiatric disorder. "A" meant almost certain psychiatric disorder, qualitatively. "B" meant probable psychiatric disorder. "C" meant doubtful—one could not tell for sure if there was psychiatric disorder or if the person was free of it. "D" was the opposite of "A"—the person showed no evidence of disorder and, moreover, showed evidence of good functioning.

Although this scale resembles the Swedish scale, it was used on the questionnaire and other data rather than on impressions gathered in a direct clinical interview. It is a much less mixed scale than that of the Midtown study, the points of which were determined by a combination of symptoms and degree of impairment.

The final judgment in the Stirling method was an estimate of the amount of impairment in functioning due to the psychiatric disorder. This judgment was made for each symptom pattern listed and also for the person as a whole. Levels prescribed in the A.P.A. *Manual* were used, but the measure of impairment was *inadequacy in life situation by reason of the psychiatric symptoms* rather than intensity of psychiatric symptomatology.

Correlations were made between the various psychiatric findings and age, sex, occupational rank, education, religion, ethnicity, marital status, and level of integration of the community of residence. Like the other two studies, the Stirling County study showed an increase in psychiatric disorder with age (the range was 20 to 80+ years), though there was a decrease after age 70. (Recall that the Midtown age range was 20 to 59 years.) There was considerably more psychiatric disorder in women than in men but little difference in impairment. There was a linear relationship between psychiatric disorder and occupational rank (like SES in Midtown), but a curvilinear relationship between psychiatric disorder and education (which formed part of the SES rating in Midtown). In keeping with hypothetical expectations, the findings also showed a significant difference in prevalence of psychiatric disorder between socio-culturally integrated and disintegrated communities. The over-all findings, corresponding roughly to what have been listed for the other studies, are shown in Tables V and VI.

Evaluation. Here, then, are three studies of the prevalence of psychiatric disorder. The most striking

conclusion from examination of the tables of findings is that they cannot be directly compared, due to differences in method and terminology. To overcome this difficulty, a calibration is now being made between the Swedish and Stirling studies in which 200 randomly selected adult records from Sweden are being evaluated by the Stirling method. If this proves useful, it is hoped that the same kind of calibration can be done between Stirling and Midtown.

Perhaps the next most striking thing is the high prevalence of whatever it is that is variously described as indicating psychiatric disorder. Between one third and two thirds of the populations studied showed symptoms of disorder recognizable by psychiatrists either from direct clinical contacts or from evidence in written records. Thus, the general impression is that the findings of these large scale investigations present a profound challenge to public health concepts regarding the nature and extent of psychiatric disorder. Or, put in another way, granted that one third to two thirds of the population are in some sense psychiatrically sick, are they sick enough so that there is a public responsibility to try to provide treatment for them?

Determining illness. To get some grip on this question of service requirements, one must make a very careful investigation as to whether those people who are sick in the sense of having symptoms of

various kinds and amounts are really sick in the clinical sense. This is the problem of the validity of concepts of psychiatric disorder used in the studies discussed, and finding a solution to the problem must be one of the major aims of future research programs. Do the symptom patterns or mental health ratings of various kinds really constitute dependable entities? To what extent would they be recognized by competent clinical psychiatrists as identical with diagnostic entities? Do they have a predictable life history? Are they influenced in a regular way by improvement or deterioration in the sociocultural climate? What level of impairment can be used to discriminate those who require treatment? How do persons rated at various points on the scales appear to a clinician? An attempt to divide up the A and B Stirling County ratings with such considerations in mind can be seen in Table VII.

Environmental factors. Related questions having to do with the environment arise from differences reported from the three studies as to what segments of the population show more and less psychiatric disorder. The two rural researches, for example, found a sex difference, whereas the urban group mental health ratings did not. Both Stirling and Midtown reported a linear relationship between mental health and economic position, yet different items are included in the estimation of the economic position, and one of them (education), taken separately, shows a different relationship in Stirling. In Midtown, SES appears to be the strongest single variable, whereas in Stirling SES is not so strong a factor as sociocultural integration. A number of other questions need to be investigated: (1) Is there an inherent difference between rural and urban populations in the importance of such things as SES, or are the differences methodological? (2) What features of SES and of sociocultural integration are crucial in their relationship to mental health? (3) How can integration be indexed in a city, and to what sort of units of population does it apply? (4) Once indexed, does it have the same mental health relationships in a city as it does in a rural community? (5) Exactly how do these group correlations operate in individuals?

There are many other unanswered questions, but those given sketch the sort of information needed to understand the implications of research already done on mental health and social environment. A review of this work, prepared by Tsung-yi Lin and C. C. Standley, has been published by the World Health Organization.

Biosocial Variables Influencing Mental Health

Man has long speculated about the cause of mental disorder. Everywhere at times, and in many cultures even today, it has been supposed that severe mental disorder, such as psychosis, was due to possession by a spirit. It has also been quite generally recognized that a person may be out of his mind temporarily with certain fevers, after trauma to the head, in the last stages of old age, or after ingestion of certain drugs. Most peoples have also taken note of various degrees of what we now call mental deficiency or mental retardation. Where survival is marginal, children suspected of retardation have sometimes been destroyed; under other circumstances, they have sometimes received preferential treatment. There is great variation in ascription of cause, classification, level of social tolerance, and treatment of mental disorder in various societies. Recognition, study, and treatment of other types of disturbance—such as personality disorders, neurotic manifestations, and sociopathic behavior—have been mostly limited to Western or Western influenced cultures.

To the general Western public, as to most of the world, psychosis is the type-specimen of mental illness, a concept that makes people unwilling to think that they or their friends can be classified as mentally ill, though it is fairly acceptable to learn that they have emotional or nervous problems and to submit to treatment for them. Since the greatly increased use of psychiatry by the armed forces during World War II, there has been a tremendous growth in the perception and acknowledgment of nonpsychotic disorders by the public, especially the middle and upper classes, and a growing realization of the relationship between such manifestations and the sufferers' way of life. There has been a widespread movement to improve the lot of the mentally retarded by special classes and training schools, and attention has been given to ways in which the increasing disabilities of old age can be ameliorated.

Psychiatry as a discipline has had to exert itself to keep up with new evidence regarding the probable importance of various social roles, occupational roles, etc., in the genesis of psychiatric disorder and regarding new means of intervention to relieve stresses and to make psychiatric assistance readily available to those who need it. It is difficult for those acquainted with Western psychiatry for only 10 or 15 years to realize the revolution in psychiatric thinking and practice that has taken place since World War

II, particularly with regard to the importance of causal factors external to the patient.

Ideas of the variables that affect mental health are derived from many sources: psychiatric, psychological, sociological, and anthropological. In each, they have different bases—theoretical, empirical, clinical, and impressionistic. Systematic discussion is difficult because of different levels of abstraction, different technical language, and differing orientations. A. Leighton has attempted to organize the variables into one comprehensive statement that not only lists and describes them but shows their interconnections. This constitutes Volume I of the Stirling County series and includes a systematic statement of a set of propositions that have a logical relationship to each other and so offer a basis for hypothesis testing and theory building. The Stirling study itself is a partial effort to do just this, and the revisions of the propositions and reemphasis suggested by the experience are treated in the last chapter of Volume III of the series. The pages that follow do not attempt to summarize the more systematic treatment but rather offer a series of general comments.

Culture. Speaking in the broadest terms, one could say that most, if not all, of the external factors mentioned above are cultural. In this sense "culture" means the total way of life of a given group of people—Western/non-Western, hunting, agricultural, industrial, etc. Obviously, however, a large part of the total way of life of a population living in a given geographic environment will closely resemble that of any other group living under similar circumstances. Eskimos are a ready example of a people whose subsistence patterns are largely dictated by arctic conditions, yet various subgroups of Eskimos have developed rather different nonsubsistence patterns, and Eskimo culture as a whole differs in many respects from that of Athabaskan Indians or Lapps, for example, who also live in northern latitudes. Therefore, "culture" is here limited to those aspects of the way of life of a given population that *sets them apart as different from other groups*. Later, various aspects of total culture are discussed separately.

A number of descriptions of dramatically abnormal behavior have appeared in the writings of anthropologists and travelers from time to time, sometimes similar behavior with different names in very different places, such as *latah* from Malay, *imu* from Japan, and arctic hysteria from Siberia and Eskimo country. These terms apply to behavior that is frequently characterized by involuntary imitating, automatic obedience, shuddering, and fright. Women suffer from such a disorder more often than men, and in some groups the victims are teased by others, who cause them to perform culturally proscribed acts by manipulating the disorder. Another example is the windigo psychosis described by Halliwell and others among the Ojibwa Indians, in which the individual feels impelled to imitate the mythical

activities of a cannibal deity. There are also historical accounts of the "dancing madness" in Japan and in Europe in the Middle Ages; many others could be cited.

Explanations advanced for such behaviors have dwelt on their uniqueness and their limitation to a given cultural group. As knowledge has increased, however, and as investigators with psychiatric sophistication have actually observed individuals with the conditions described, doubt has arisen that there is very much uniqueness beyond a cultural flavor and coloring, such as Laubscher described for the hallucinations and delusions of Bantu schizophrenic patients.

On the physical side, it has been suggested that culture may influence the occurrence and type of psychiatric disorder in various ways. In a small group, not more than a few thousand, that is isolated from other groups, it is conceivable that some basic personality type especially vulnerable to psychiatric disorder may arise, due to the influence of inbreeding. Such a group may develop child-rearing practices that, according to tenets of Western psychiatry, would tend to produce malfunctioning adults. By ignorance of nutritional needs, sanitation, and hygiene, a people could undermine their health and lay themselves open to parasitic or bacterial infestation.

On the social side, the mental health of one sex may be jeopardized by the overvaluation of the other sex. Or where the shame mechanism is utilized to produce conformity, it may give rise to disorders of a particular kind, in contrast to a culture where conscience is inculcated and produces feelings of guilt for nonconformity. Or sanctions against particular acts—such as incest, improper behavior during menstruation, or giving birth to twins—may be so strong as to lead to suicide or murder of the offender. The ultimate is perhaps the psychological death described in several cultures, where a person, out of harmony with his culture, dies without any discoverable physical or physiological abnormality.

It has been suggested that some cultures foster mental disorder by rewarding disordered individuals with prestige roles. This usually refers to the medicine men or shamans who conduct religious rites and deal with the care of the sick. The idea appears to be based on observations of ceremonies in which trancelike or epileptic-like behavior is part of the procedure. The weight of evidence in recent studies, however, suggests that such behavior is not pathological.

Finally, it has been charged that some cultures produce mental difficulties for their members by an overabundance of stressful roles. These may be stressful because of ambiguity regarding expected behavior, because of inherently conflicting standards, or for numerous other reasons. In the light of present knowledge, it seems that such a state of affairs indicates

that the culture is undergoing transition due to either internal or external pressures. It appears, in short, that a well integrated, vigorously functioning culture presents a satisfactory balance, in at least a majority of its roles, between elements that make the position stressful on one hand and some balancing compensations on the other. The notion of a preponderance of pathogenic roles or practices seems untenable except where the whole culture shows signs of disintegration. Investigations of societies where slavery or a rigid caste system prevails would furnish evidence on this hypothesis.

It seems fairly clear that culture change can be quite devastating to the mental equilibrium of group members. Where the change is rapid and pervasive, many discontinuities develop—children continue to be reared by techniques that were appropriate for conditions no longer present; certain roles, once matched by compensations, become intolerable; traditional values no longer serve as adequate guidelines. At present, it is not possible to state how culture can change without these undesirable consequences, but it seems likely that, in time, an understanding of the details of the process and of the prerequisites necessary to success will develop. Many instances can be quoted where a marked change has taken place without apparent damage and of others where apparently slight change has wrought havoc. Suggested ameliorative factors are a flexible personality structure; an adequate level of cultural integration, which implies the availability of satisfactory leadership; and some sort of programming of change over time, so that the old ways are not discredited until substitutes can be offered.

Sex. This feature of an individual might be considered relatively culture-free. It is a biological attribute, to be sure, but a moment's reflection brings to mind the infinite complexity of cultural rules and regulations related to sex. A little boy in Western society should not be allowed to play with dolls, for example, nor should a man prepare himself for a vocation commonly filled by women; first or even second cousins should not marry; inheritance may be limited to the maternal or paternal line, and so on. However, Western society tends to be quite lenient regarding roles suitable and allowable for men or women as compared to many other societies.

What, then, is the significance of sex in relation to vulnerability to psychiatric disorder? It is not easy to assess this from mental hospital statistics because there are commonly an equal number of beds for men and women patients, and both are fully used; in addition, many selective factors determine who goes to the hospital or to someone for treatment. Population studies have to be examined for this information. In the Midtown study, no difference was found in the over-all prevalence of psychiatric impairment in men or women, but the women reported a greater number of psychoneurotic and psychophysiological symp-

toms. In the Swedish study and the Icelandic study (Helgason), the prevalence was slightly higher in women. In the Stirling County study, over-all figures showed a considerably higher prevalence in women; an even greater prevalence in women was seen in one carefully studied community and a higher prevalence in men than women in a second carefully studied community; in three communities the sexes were about equal. In some Nigerian Yoruba villages surveyed (Leighton et al., 1963), the men showed a slightly higher prevalence. Hinkle and Wolff have reported higher prevalence of mild disorders of all kinds in women but more serious impairment in men in two homogeneous groups of men and women in an industrial setting.

These data may strike the reader as "hit or miss" inconsistency, but careful scrutiny of related sociocultural features provides some plausible explanations. Mental illness in the popular sense is comparatively rare in all populations—less than 5 per cent—and the types of psychiatric disorder recorded are chiefly psychophysiological, psychoneurotic, personality disorder, and sociopathic behavior.

Looking first at Nigeria, it seemed quite obvious that the village men were in a difficult position because they were being subjected to considerable pressure to master European ways; at the same time they were required to perform as traditional Nigerians. The village women, on the other hand, were very little affected as yet by Europeanization. They were acting as they had been trained to act when they were little girls, and life had turned out about as they had been led to expect. Assuming that the kind of psychiatric disorder reported may be an evidence of stress on the individual, it is not surprising that the men were more affected than the women.

The Stirling County ratios may be taken as an indication that culture change is being experienced more acutely by the women than the men in the county as a whole and in the one village cited. This is very probably the case for large portions of the North American continent at this point in history, where the world of women is expanding and woman's role is much more ambiguous and full of conflict than a few generations ago. Like the Nigerian men, they are caught between the old ideals of being a good wife and mother on the one hand, the urge to find application for skills developed through their increasing education on the other, and, in some cases, the need to supplement the family income.

But what, then, of the village with the reverse ratio between the sexes, or the disintegrated communities where women and men are about equally affected? Available evidence indicates that the women in the Stirling County village were healthier than the men at the time of the survey for much the same reasons that the Nigerian village women were healthier than the men—the changes that had already affected the men had not yet impinged on the women.

Because of various historic and economic events, the men had had to alter their values and practices to a considerable extent, whereas the women were able to continue to function according to the habits and ideals of their youth. In the disintegrated communities, on the other hand, both men and women appeared to be reflecting, in the psychiatric disorder they demonstrated, the severe deprivation in virtually all areas of life to which they were subject.

The lack of statistically significant difference in prevalence of psychiatric impairment between men and women in Midtown may indicate that, as in the depressed Stirling communities, stresses are approximately equal, though not necessarily identical in nature, for the two sexes. In Sweden and Iceland, greater difficulty experienced by women can perhaps be explained by much the same reasons as suggested for the women in Stirling County as a whole.

This discussion leads to the conclusion that there may be nothing specific about either the male or the female sex that predisposes an individual to develop psychiatric disorder. What makes most of the difference is probably the interaction of sex with various features of any given culture, which may serve to place men or women in an advantaged or disadvantaged position. This, in turn, may protect or expose the sex as a whole to stresses leading to symptom formation.

Age. This, again, is a biological attribute of mankind. Most investigators have found that the proportion of the population showing evidence of psychiatric disorder increases with age. A few conditions, such as chronic brain syndrome, are more or less age-bound.

In his study of the Texas population in 1951-1952, Jaco showed that the incidence rate increases more rapidly with age for women than for men up to the 45 to 54 decade, after which it decreases until the oldest group; for men there is a more gradual but steady rate increase with age. Undoubtedly, many other factors besides age play a part, such as childbearing and child rearing in the women between 15 and 54. The decreasing economic and occupational importance of men after age 55 to 64 may have an effect on the increase in their rate (see Table VIII).

From the Midtown study's treatment census, opposite age trends are found between hospitalized in-patients and clinic out-patients (see Table IX).

Compared with this, one finds that the percentages with various degrees of psychiatric difficulty in the general Midtown survey population shift from predominantly well or only mildly affected in the earliest decade to a slight excess of the dominantly impaired or moderately affected in the oldest decade, with an intermediate plateau for the decades between (see Table X).

From the Swedish study and the Stirling County study similar findings emerge. Table XI expresses them in arbitrary units in which 0.50 represents the

whereas the Swedish group risk gradually increases with age. One cannot say what the Midtown trend after 60 would have been, owing to the cut-off age of 59 years.

This accumulated evidence points to a relationship between mental health and age, but it is not a direct and simple relationship. In every set of figures quoted, the best mental health occurs in the youngest group or groups, but in some populations there is a peak of psychiatric disorder in the middle ages, followed by a subsequent decrease; in others there is a steady increase with age. The differences in these two arrangements might be understood if enough were known about the life circumstances of the various age groups in each population, with particular reference to stressful factors. The figures quoted, however, are too diverse in age range and in type of analysis to do more than suggest possible avenues of enquiry.

Marital status. Here we progress from what appeared to be purely biological variables, albeit complicated by cultural interferences, to a very mixed biocultural one. There are few if any cultures in existence that do not specify in some way who may or must marry whom, how the change in status from single to married shall be signalized, and the obligations of the married pair to their families of origin and to their family of procreation. There is, of course, a considerable variety of patterns: monogamy, polygamy, matrilineal or patrilineal ties, extended families and unitary families, stable and unstable marital arrangements, great emphasis on economic or familial connections in picking a partner versus equally great emphasis on personal choice and attraction, greater or lesser restrictions on premarital and extramarital sexual relations, and so on. It is safe to say that there is no universally ideal pattern, for each culture has developed a set of marital customs and expectations that are interwoven with other aspects of life and could hardly be expected to suit members of some quite different culture. Nearly any pattern would succeed under the right circumstances.

It is common for members of Western culture, where monogamy is the ideal, to view polygamous

arrangements with horror. Seen in context, however, where emotional ties between husband and wife are usually not so strong as between mother and child, where additional working members of the family are a necessity for subsistence, and where both men and women grow up with the notion that this is a natural social configuration, polygamy seems quite as satisfactory as monogamy, which may bring with it strong and hampering emotional dependencies, suspicion of the spouse's fidelity, and the need to cope with life's problems with the help of only one other person. In short, neither type of marriage can guarantee an ideal mental health setting for its members. A good case can be made for either under suitable circumstances.

It is safe to say, however, that the commonest state for adults in most cultures is to be married in some fashion, so that adults who have never married and those who have married and given it up may be considered deviants. Widows and widowers are, perhaps, in a somewhat special category, since choice does not usually enter into the ending of their marriages. There is a popular idea that there must be something wrong with one or both of the partners who break up a marriage, but the status of one never married is not judged so clearly.

Jaco says of his psychotic subjects in Texas:

Annual incidence rates adjusted for age, sex, and subculture were found to be highest for the divorced, followed by the rates for the single, the separated, the widowed, and the married. . . . For the divorced, incidence rates were highest for not only the entire population, but also specifically for both sexes and among the Anglo-American and nonwhite groups. . . . One explanation that has been given for the higher incidence of mental disorders among the divorced than the married population is that a prepsychotic person, or an individual who is basically unstable and therefore 'difficult to live with,' is prone to marital instability and subsequent divorce. While this explanation has merit, it is also possible that any prepsychotic individual may not actually manifest a mental illness until the trauma of divorce occurs or the experience of breaking the marital bond takes place. In this formulation, the condition of divorce can be regarded as a social precipitating factor for such predisposed individuals in the onset of their psychiatric disorder.

From other studies a number of interesting findings have emerged. In the Midtown study, for example, it turned out that the mental health status of never-married women was approximately the same as for married women but that approximately twice as large a percentage of never-married men had been rated "impaired." The suggested explanation is that bachelors are more likely to have been actively rejected in the marriage market, presumably due to some obvious shortcomings, but spinsters may either have preferred their state or just not have been chosen, due to a plethora of women. Widows are about as healthy as wives. Table XII shows that in New York City, at least, divorce and poor mental health are closely associated.

The Stirling County study found no significant differences in mental health status associated with

marital status, although the use of a sample of heads of households slanted the subjects chosen in the direction of married people and may have distorted the picture. In comparing the marital status and mental health status of the Swedish sample with a systematic sample from one Stirling County community, however, some interesting contrasts appeared. In both communities, about three quarters of the sample are married. Among the unmarried in the Stirling County town, approximately equal proportions are single, divorced or separated, and widowed. In the Swedish sample three quarters of the unmarried are single, a fifth are widowed, and the small remainder are divorced or separated. Arrangement of married, single, separated or divorced, and widowed in rank order, for both mental health status and average age, shows that the differences are not due to an age effect (see Table XIII).

In each community, the group with the best mental health has the next to highest mean age, whereas the preceding section regarding age has indicated that better mental health is usually associated with younger age. The Swedish widows have the poorest mental health and are the oldest group, which is congruent with general findings related to age, but in the Stirling County community the separated or divorced group, with the worst mental health, are next to youngest. One cannot state with assurance all the significant aspects of these findings, but one can say that any given marital status seems to have different social and emotional significance in these two populations and seems to differ in mental health status from what one would expect, considering the mean age of people in a status and the relationship between age and mental health noted above.

Socioeconomic or class position. Differentiation of a cultural group into levels of influence or affluence or both is nothing new in the history of the world. It is, in addition, a very widespread characteristic of populations, usually less obvious in small groups than in large groups. Industrialization tends to emphasize such a stratification by its need for different degrees of skill and education and by its corresponding granting of rewards. In nonindustrial cultures, the basis for differentiation is more likely to be family lines, power, prestige, or special abilities, such as those for oratory, for learning the religious lore, and for being able to communicate with supernatural powers. A clear stratification of classes is mostly restricted to cities and their surrounding suburbs in an industrial culture; rural populations tend to be more egalitarian.

Many books have been written about class differentiation characteristics, suitable ways of indexing, and so on. Two of the classics, widely used by others, are those of Warner et al. and Hollingshead and Redlich. Another recent treatment of the subject has been provided by Kahl. National censuses have commonly made distinctions on the basis of income and of occupational type, starting at the top with

^b Best health, youngest age.

professionals and ending at the bottom with unskilled laborers. Intermediate ranks are usually semiprofessional, skilled, and semiskilled, but the definitions of the specific occupations included are not always the same in various censuses. The disposition of unemployed women poses a problem that is usually handled by classifying them according to the level of their husbands. Due to the lack of any clearly preferable scheme, many investigators interested in the relation between mental health and socioeconomic position have adopted the local census standards. In addition to being ready made, use of census definitions facilitates comparison of the sector of the population under study with the entire national group.

In a review of "25 or more attempts to count untreated cases of psychological disorder in community populations," the Dohrenwends noted that there

is no uniform relationship between judged psychopathology and age, sex, or race. Following the earlier discussion of the relationship between age, sex, and psychiatric disorder, their review supplies additional evidence that age or sex alone are not determining factors. They added: "Against this background of inconsistent results, it is almost startling to find that 14 of the 18 studies which present data on the relationship with social class yielded the highest rate of judged psychopathology in the lowest economic stratum. . . . Only one study reported the highest rate in the highest income group." The studies cover certain rural and urban populations in North America, northern Europe and Asia. The reviewers went on to say that "a relationship of such apparent strength must command attention. The cumulative evidence it represents appears to establish the association of low socioeconomic status with a high rate of judged psychopathology as an important source of working hypotheses."

It may well be that such a strong and widespread association indicates the supranational character of industrial development, which imposes a set of socioeconomic levels and values wherever it becomes established. It would be instructive to discover the relationship between psychiatric disorder and the lowest level of some hierarchy based on a noneconomic principle. In most populations, there is a coincidence of low social position and low economic position that makes it difficult to determine the effect of either alone. In Iceland, where, Helgason said, social class differences are negligible and where wages are more uniform than in most other countries, there is little difference in over-all expectancy of psychiatric disorder between classes.

A particularly interesting finding comes from the community in Sweden that Essen-Möller and Hagnell studied, where the relationship between socioeconomic level and psychiatric disorder is reversed, and the lowest level has the least risk of disorder. The conclusion seems inescapable that, at least in this community, Swedish social legislation and cultural attitudes have removed many of the difficulties that exist elsewhere for those at the bottom of the economic heap.

Studies related to the problem of poverty have shown repeatedly that it is not only lack of money but also lack of nearly all the advantages associated with money that make the position of the poor so hampering. A great challenge to Western society is to discover how to deal with the problems of this group in a constructive way, bringing to bear all the techniques and understanding that behavioral scientists have developed in modern times.

Sociocultural integration. The final variable to be discussed here for its relationship to psychiatric disorder has received attention in only two investigations in any systematic way, the Stirling County study and the Yoruba study. It approaches the first

variable discussed above, culture, but is an aspect or quality of culture, not the whole; nor is it a section of culture like religion or socioeconomic structure. It is conceived to have an over-all pervasiveness that affects all aspects of the culture. It is hypothesized that small homogeneous communities as units of culture can be placed on a range of integration from near zero at one end (disintegration) to a well functioning societal system at the other end that provides adequately for the sociocultural needs of its members (integration). So far, in Stirling County publications the theory and concepts of social disintegration have been applied only to small, quasi-organismic communities. Adaptation and modification of theory are necessary when it is applied to larger, more amorphous social systems.

To find where a community belongs on this range, one may use various sociocultural indicators: the poverty-affluence dimension; the over-all coherence or confusion of its culture values; the viability of its religious system; the stability of families; leadership and followership; communication networks; supportiveness of interpersonal relationships; etc. In homogeneous communities one commonly finds that there is a tendency for a given level on one axis to intersect many axes at about the same level—that is, if there are stable families, in all probability there will also be clear cultural values, religious activity, adequate leaders and followers, good communications, a reasonable economic level, etc. Conversely, in the presence of general poverty, one is likely to observe uncertain and variable cultural values, little interest or participation in religion, many broken families, unclear or absent leadership, poor communication, suspicion and hostility between individuals, and so on. Or most of the axes may intersect at some intermediate level.

In the Stirling County study, it was postulated that mental health would be best in an integrated community and worst in a disintegrated one. This was tested by selecting sample communities of each type as near the extremes as possible and surveying the mental health status of a sample of the population in such a way that the psychiatric judges did not know the kind of a community from which a given subject came.

The findings both in Stirling County and among the Yoruba supported the hypothesis to the extent that mental health was considerably better in the integrated than the disintegrated communities. A corollary of this hypothesis is that, if the integration status of a community improves, so will its mental health. This also took place in one disintegrated community in Stirling County over a period of a few years, which further strengthens the probability that sociocultural factors stand in a causative relationship to psychiatric disorder in populations. It seems likely that the reason the study of this aspect of mental health has received so little attention is

that few studies have been done with the aid of social scientists. The extensive work required to assess the indicators of community integration calls for more social scientific training than most psychiatrists, who have been the investigators in other studies, possess. In the Midtown study the nature of the community precluded assessment of its integration in the sense that it was done in Stirling County. Currently, however, an attempt is being made to study units of the metropolis that can be contrasted as to their state of relative sociocultural integration.

Goals

It seems clear that a start has been made toward approaching the goal of understanding that aspect of human functioning that we call psychiatric disorder against the background of biosociocultural features that constitute man's life experience. Concepts are still groping and faulty, their development hindered by a weight of traditional blind spots and biases. As concepts become more adequate, it will be possible to plan more crucial and enlightening investigations, utilizing the modern tools and methods that enable researchers to deal effectively with complex data. Much can be gained, even in the present stage of conceptualization, by accumulating systematic, comparable data on diverse human groups to test out the degree of regularity with which findings such as have been reported above occur around the world. Adoption of a common terminology for describing the findings will speed the formulation of new concepts and the delineation of the human universals. It is quite possible that a new classification for both psychiatric disorders and sociocultural features may result from more extensive researches.

The pertinence of such studies lies partly in their power to enlarge understanding of human behavior in more of its complexity than can be handled at present and partly in the leads they provide for dealing with psychiatric disorder by sociocultural rather than individual clinical means. The latter possibility can be viewed as partly therapeutic, partly preventive, and can be expected to play an increasingly important role in such activities as urban planning, community development, relief of the condition of poverty, and control of cultural change.

Suggested Cross References

See Section 5.1 for further information regarding the epidemiology of psychiatric disorders. For discussions regarding some fundamental concepts of cultural and social determinants of behavior, see Sections 4.1 and 4.2.

45.4 UNITED STATES COMMUNITY MENTAL HEALTH PROGRAM

STANLEY F. YOLLES, M.D.

The emergence of the theory and practice of community and social psychiatry, described in this chapter, was coupled with an attempt to establish coordinated community services and facilities which would provide comprehensive care for the mentally ill. This movement achieved the status of a national program with the passage of the Community Mental Health Centers Act of 1963. According to current projections, by 1970, approximately 500 of these centers will be in operation, and each will serve the mental health needs of the entire population of a given area.

The appearance of a community network of psychiatric facilities on the American scene for the first time in history may be attributed, in large part, to modern psychiatric research and increased clinical experience. In the course of their clinical efforts, psychiatrists have learned that in many cases early diagnosis and intensive treatment of acute psychiatric illness may obviate the need for long term hospitalization. It has also been hypothesized that efforts to prevent mental illness can best be implemented through a community system designed to provide psychiatric consultation to all of the community's helping professions. Recent trends in psychiatric education reflect these developments. Psychiatric training institutions have begun to include "community psychiatry" in their curriculum as an essential. And this exposure, however limited it may be at this point, serves to orient the psychiatrist of the future to a new facet of psychiatric practice. These events have broader implications as well. They indicate a wider acceptance on the part of the profession of a public health approach. And, in fact, increasing numbers of psychiatrists are beginning to recognize the need to develop the skills which will enable them to help large groups of people.

Mental Health Center Legislation

Provisions. Through The Community Mental Health Centers Act of 1963, mentioned above, the 88th Congress authorized the appropriation of \$150,000,000, over a 3-year period, to finance up to two thirds of the construction costs of any one mental health center program. Regulations governing the award of these construction grants have been issued by the Secretary of the Department of Health, Education, and Welfare. The National Institute of Mental Health administers the program aspects of aid to the centers; and the Division of Hospital and Medical Facilities, Public Health Service, administers the technical aspects of construction.

On August 5, 1965, President Johnson signed into law an amendment to the Act, providing additional federal funds to help pay the cost of staffing the centers during the initial years of their existence. This financial aid is available on a gradually decreasing percentage basis, and is earmarked for the operation of new centers, or for the financing of the expansion of an established program. Thus, the amendment is designed to help the centers cover the costs of professional and technical personnel during the interim period while states and communities work out more permanent funding patterns.

History. *Action for Mental Health*, the report published in 1961 by the Joint Commission on Mental Illness and Health, and, more specifically, the Commission's recommendation that preventive and treatment services be instituted on a local community level, played a major role in the adoption of mental

health centers legislation. The Commission's recommendation was precipitated by a number of factors.

Foremost among these were the demonstrated success of open hospitals and day and night hospitals in the treatment of psychiatric patients; the development of psychoactive drugs which permitted the treatment of many patients in their communities or their return to the community after a relatively brief period of hospitalization; the increased use of the inpatient services of general hospitals for the treatment of acute psychiatric illness; the growing number of out-patient clinics; and the expansion and extension of psychiatric knowledge. Psychiatric research over the past 2 decades has illuminated the possible role of genetic, social, and biological factors in the onset of mental illness. But, in particular, research findings have highlighted the importance of early life experiences and of interpersonal and sociocultural forces in shaping character, personality, and behavior. Concomitantly, psychiatrists have become increasingly concerned with the impact of the family and the community upon the individual.

This key concept—which is a cornerstone of the community mental health approach to treatment and prevention—was stated eloquently many years ago by Dr. Adolf Meyer. Dr. Meyer believed that the proper domain of psychiatry was the behavior of the whole man, as a manifestation of his reactions to environmental stress—past, immediate, and potential. Dr. Meyer explained his position in 1928, in reminiscing about his work in a state mental institution in 1904:

I had to reach out, in my actual work, more and more to a broader understanding of the patients, which led me to a study of the family settings and by and by also of the place where the individual first became a member of the community. The school . . . the life of the patient and of the family, the life of the patient in hospital, and the return to the community began to receive more practical attention. . . .

The adoption of mental health centers legislation was also fostered by the fact that the Commission's recommendations were made public at a time when the nation was beginning to regard mental illness as a public health problem. On one hand, state and local legislators, who had become increasingly concerned about the mounting costs of prolonged hospitalization of mental patients, encouraged the use of alternative types of care. Indeed, in many states, community mental health services acts were enacted under the joint financial support of the state and the local community. On the other hand, the community was better prepared to accept the idea that it might care for its mentally ill citizens without endangering its "healthy" citizens.

This changing attitude was reflected in the unprecedented Message on Mental Illness and Mental Retardation which President Kennedy delivered before the 88th Congress on February 5, 1963. The study of

the Joint Commission had been reviewed by a Presidential committee and Kennedy summarized its conclusions: "Government at every level—Federal, State, and local—private foundations and individual citizens must all face up to their responsibilities in this area."

Congress acted promptly in response to this appeal. A series of Congressional hearings was held at which leading authorities in psychiatry and related fields, including representatives of the American Medical Association, the American Psychiatric Association, the National Association for Mental Health, the Public Health Service, the Veterans Administration, and other organizations and agencies, expressed their wholehearted support of a nationwide program of community mental health services.

The Community Mental Health Centers Act, as well as several other measures of federal support, grew out of these deliberations. The National Institute of Mental Health was authorized to support projects for the improvement of state hospitals and institutions for the mentally retarded. The Institute was further authorized to expand its training program and to provide support for in-service training, focusing first on the training of ancillary hospital personnel who were directly responsible for the care of the mentally ill.

Structure and Organization of the Mental Health Centers Program

Above all, embarking on a national program to effect a widespread change or, more accurately, a revolution in the nation's established modes of providing care for the mentally ill, required sound planning. To this end, Congress appropriated a total of \$8,000,000 to underwrite comprehensive state mental health planning throughout the nation. Accordingly, preliminary outlines for planning procedures were drafted in every state and territory. Each state then surveyed its mental health needs and resources and, on the basis of these data, evolved comprehensive, long range plans for mental health services—a step unprecedented in any field of health. More than 25,000 psychiatrists and leaders of allied professions, State Mental Health Authorities, and members of State Departments of Health and Mental Health participated in this planning. And in at least 22 states, governors established special mental health task forces.

These comprehensive plans were followed by state plans for the construction of community mental health centers. Each state recommended that specific centers receive priority for federal support. By July, 1965, the first applications for federal construction aid had been reviewed by the National Institute of Mental Health.

The elements of community mental health services. To a significant degree, deliberations regarding the new mental health program focused on the types

of services to be offered through the centers. Previous experience with community mental health services and demonstration studies pointed to the need for at least five basic, or "essential" services. As defined by law, these include: (1) in-patient services; (2) out-patient services; (3) partial hospitalization services, such as day care, night care, or weekend care; (4) emergency services, available 24 hours a day, within at least one of the above services; and (5) consultation and educational services, available to community agencies and professional personnel.

In addition to these essential services, comprehensive community services also include: diagnostic services; rehabilitative services, including vocational and educational programs; pre-care and after-care services, including foster home placement, home visits, and halfway houses; training; research and evaluation. In light of this wide range of services, the mental health "center" might be described more precisely as a mental health "program" or "network" of services. Not surprisingly, the diverse services provided by the center are not necessarily under one roof.

Philosophy and goals. Nevertheless, the key to the system of community mental health centers is the integration of these varied services. Thus, while they will demonstrate inevitable physical differences, these centers share in common the essential quality that these services are so organized as to form a coordinated system of care. This arrangement makes it possible to provide patients with the specific type of service they require, depending on the intensity and stage of their illness. Moreover, when such services are provided within a community setting, treatment will cause only minimal disruption in the life of the patient and members of his family.

Another goal of the community mental health center is the prevention of mental illness through the provision of consultation services to nonpsychiatric physicians, teachers, clergy, representatives of the law, and others who are in a position to detect emotional difficulties in the people they serve. From a public health viewpoint, the problem of mental illness cannot be alleviated sufficiently by individual or group treatment alone. Professional consultation services as well as educational programs for the layman are considered, therefore, to represent essential aspects of the center's program.

The community system also seeks to bring the care of the mentally ill back into the mainstream of American medicine, where many psychiatrists believe it belongs. Thus, as mentioned earlier, in many community programs, the general hospital is utilized for the in-patient treatment of the psychiatric patients. Federal regulations encourage the participation of nonpsychiatric physicians in mental health centers also. More specifically, they are to be permitted, when qualified, to assist in the psychiatric care of their

patients, under the supervision of a member of the psychiatric staff, and, in any event, they are to be kept fully informed of their patients' progress. The advantages of close liaison between the psychiatrist and the family physician and the ways in which the system of community care encourages this liaison have been indicated elsewhere in this chapter. It may be added here, however, that the community mental health centers program as conceived in the United States is the instrument, and provides the facilities for this liaison, as well as for the emerging practice of community and social psychiatry.

Finally, a federal requirement of vital interest to both psychiatrists and the general public is that each mental health center must provide psychiatric care for everyone residing within the community served, regardless of length of residence or ability to pay for such services, and without discrimination as to race, color, or creed. As defined in federal regulations, a "community" has a population of from 70,000 to 200,000. Consequently, in several regions, centers serve the residents of more than one state, under interstate compacts.

Community Mental Health Centers versus Separate Services

The question is sometimes raised as to why, in view of the rapidly expanding number of out-patient clinics and other psychiatric facilities provided by the general hospital, it is necessary, or desirable, to undertake the community mental health centers program on a national scale. Many of the advantages of coordinated and comprehensive facilities are embodied in the federal regulations governing awards for construction aid. These programs have taken into account the needs of all age groups; and they are designed to ensure the integration of individual types of service according to the following criteria:

- that any person eligible for service within any one element of service will also be eligible for treatment within any other element of service;
- that any patient within any one element can and will be transferred without delay to any other element (providing that adequate space is available) whenever...indicated by the patient's clinical needs;

—that clinical information...obtained within one element be made available to those responsible for that patient's treatment within any other element;

—that those responsible for a patient's care within one element can, when practicable and not clinically contraindicated, continue to care for that patient within any of the other elements; —and that in cases where two or more of the individual elements of services are provided by different organizations, agencies or persons, the relationships between the individual elements must be evidenced by appropriate...formal written agreements.

A careful review of these criteria will point up the fact that the centers program presents psychiatry with new challenges and opportunities. The psychiatrist who works in such facilities is challenged to study individuals as they attempt to adjust to a wide variety of biological and psychosocial forces and to determine, on the basis of his observations, his patients' modes of adaptation to a variety of life situations. Concurrently, the psychiatrist is given a unique opportunity not only to treat maladaptation in its earliest stages, but also to develop an effective program for the prevention of mental illness and a concomitant program for the promotion of mental health.

Chapter 46

Community Psychiatry. II: Intervention

46.1 PRIMARY PREVENTION

HAROLD M. VISOTSKY, M.D.

Primary prevention has long been a well accepted public health concept and, as such, represents a community concept. Only within recent years, however, have psychiatrists incorporated this concept into their programs for the treatment of mental illness and the promotion of mental health.

As pointed out earlier in this area, community psychiatry and social psychiatry can best be understood in terms of public health concepts. By definition, primary prevention programs in psychiatry are designed to lower the rate of onset of emotional disorder in the community, by counteracting the stressful or potentially harmful social conditions which produce mental illness, and by prompt intervention when such conditions exist. It follows, then, that a primary prevention program will necessarily involve significant members of the community and engage those institutions of our society which, by virtue of their role, have a crucial impact on the bulk of our citizenry. More specifically, with respect to the individual, the principles of primary prevention are implemented by social agencies, schools and churches, physicians and health professionals, local government leaders, and, most important, the individual's family and other significant people in his life.

In fact, the concept of primary prevention, which, as mentioned above, represents a relatively recent addition to the body of psychiatric knowledge, can be truly effective only if its principles are applied by workers at every level of community activity. The integration of such principles into the programs initiated by community workers in the areas of general health, welfare, education, housing and urban renewal, and other cadres, will, inevitably, contribute to the quality and effectiveness of these community efforts. Concomitantly, exposure to the concepts of primary prevention in psychiatry may have a sensitizing and educational effect on these cadres, so that

it will be easier to enlist their cooperation in a comprehensive program to provide early intervention in mental illness, as well as in a realistic program for the rehabilitation of former psychiatric patients. In other words, the widespread application of primary preventive measures can serve, indirectly, to facilitate the implementation of secondary and tertiary preventive efforts.

The Role of the Institutions of Society in Primary Prevention

The techniques utilized by social institutions in the service of primary prevention can best be conceptualized in terms of the three major groups in the community to whom such efforts are directed—children and adolescents, young adults through maturity and our older citizens. It must be emphasized, however, that although this structural division will serve to facilitate discussion, in fact, these three groups are interrelated and cannot be arbitrarily divided in practice.

Children and adolescents

Maternal and family-centered programs. Services provided in this area will focus on the prevention of premature births; prenatal disturbances which may lead to brain damage (including prenatal intrauterine intervention); and the prevention, through prompt consultation, of emotional disturbances during pregnancy.

The role of the general practitioner with respect to this patient population includes anticipatory counseling. That is, in general, it is the physician's task to forewarn his patients of possible "crises" in physiological functioning, and, through the process of education, strengthen their capacity to cope with these crises effectively. Clearly, pregnancy constitutes one such crisis, and his contact with parents, particularly young parents who are expecting their first child, provides the general practitioner with a unique opportunity, not only to educate and thereby prepare them for the pregnancy itself, but to shape parental attitudes with respect to their responsibility toward the child.

Through direct discussion with the general practitioner, or through class discussions sponsored by social and welfare agencies, young parents can be helped to recognize that the healthy development of their child will depend, in large measure, on their ability to gratify his basic needs. Ideally, such discussions will also focus on the struggle between dependency needs and the desire for independence which is characteristic of the growing child, as well as the various stages of development and their accompanying patterns of growth.

Participation by parents in such discussion groups and instruction in these basic, and frequently unfamiliar, concepts may have a profound effect on their future attitudes toward the problems they will inevitably encounter as their child progresses from infancy to childhood, and then to adolescence. The early education of parents seeks to foster their awareness of the psychological needs of the child which, in turn, will enable them to provide a home atmosphere which is conducive to the child's healthy development. Obviously, such an environment will help to ameliorate many transient emotional crises which are associated with specific phases of development. But, in addition, psychological awareness can also help to eliminate tensions which may produce personality distortions in the parents and eventually lead to serious maladjustment in the child, as well as his parents. Distorted relationships may obtain for some time before they reach full pathological intensity. It is during this interim period, when the situational factors which have given rise to these tensions can still be corrected, that the intervention of the family physician or pediatrician or of well baby clinics may be particularly helpful.

It is equally essential that teachers, who will bear a major share of the responsibility for the emotional well-being of the school age child and adolescent, receive some instruction in developmental psychology and the dynamics of family interaction. If the school system is to play a more active role in primary prevention, it is imperative that training be provided at a classroom level which will enable the teacher to differentiate between the use of healthy and pathological mechanisms to cope with life stresses. Concomitantly, community service agencies should make trained professionals available for consultations with teachers when problems arise involving individual pupils or groups of children.

To illustrate, a program currently under way in the Woodlawn area of Chicago calls for regularly scheduled meetings between a team of mental health educators and psychiatrists and school personnel. The purpose of this in-service training program is to sensitize teachers to the presence of emotional conflict in the children under their supervision before symptoms appear, on the one hand, and to provide consultation for teachers of children with manifest symptom complexes, on the other. In a broader sense, the

goal of the program is to foster understanding of the psychological and sociological needs of the child and to help the teacher to develop the ability to meet these needs. Thus, these professionals expand their capacities as interveners who must deal effectively with children in stress and, concomitantly, help other children to learn to cope more adequately with the stresses of our society. The well defined critical periods in school life, when the child must make the transition from primary to intermediate curriculum, that is, from the neighborhood elementary school to junior high school and high school, provide a basis for discussion, with students as well as teachers, of the problems which typically surround such transitions. In brief, case finding and screening become part of the total educational program. Finally, this program is based on the awareness that the teaching corps constitutes a sizable—and accessible—group of professionally trained persons in responsible contact with large numbers of children. As such, the potential significance of the teacher's contribution to our preventive efforts must be recognized and implemented.

We must begin to train a cadre of child care specialists who will be qualified to intervene and work with children and their families during periods of psychological crisis. A list of the candidates eligible for such training would include pediatricians and other health specialists. In addition, comprehensive training in child psychology should be provided for those professionals who work with mothers, as well as children, and who, by virtue of the nature and scope of their activities, are given a unique opportunity to promote effective child-rearing concepts and implement legislation to ensure the health of the pregnant woman.

Prenatal and immediate postnatal instruction in child development, child rearing, and family life can and must be incorporated into the community's public health and mental health programs. If education is to become an effective instrument of preventive psychiatry, mental health specialists, in conjunction with other groups, such as the professionals who staff social agencies and even specially trained non-professional volunteers, must work in the field to disseminate factual information. At the same time, it must be emphasized that a program of psychiatric education directed toward the general public requires careful planning; obviously, if the information provided thereby evokes extreme anxiety or is unnecessarily confusing, the program will be of limited value. The overriding goal of psychiatric education at this level must be the improvement of community attitudes toward psychiatry and those psychiatric services which seek to prevent emotional and functional impairment, to remove the stigma attached to psychiatric intervention, and to dispel the air of mystery which continues to surround the psychiatrist and his treatment efforts.

This type of educational program can also help the community to plan for mental health. Ideally, it will facilitate solicitation of financial support for such efforts and thereby permit the effective organization of community resources and personnel. Accordingly, the information provided within this framework must clearly discriminate between scientific and unscientific therapies; it must encompass current hypotheses on the role of heredity and constitution in mental illness, on child-rearing practices, on child development, and on the etiology of psychiatric illness in adults. In brief, it must impart knowledge which will help the individual to understand his own, as well as his neighbor's emotional reactions.

Infant-centered programs. Such programs should include systematic evaluation of all newborns, registration of all infant defects, and establishment of treatment centers for brain-damaged infants.

Programs should be set up for well baby follow-up by public health nurses and other units, organized to reach every infant in the community. It is essential, of course, that such programs provide basic instruction by mental health specialists in the psychological aspects of infant development, as well as consultation services for the professional personnel directly involved in these services. Large scale day care programs should be designed to provide an optimal psychological milieu for infants from culturally disadvantaged families. Protective services, enforced by legislative provision, will enable supervision of families with a history of severe behavioral disturbance in relation to their children, e.g., infant battering, extreme neglect, etc. Preventive programs and techniques should be developed for premature infants and infants who must remain in hospital nurseries and institutions.

Preschool and school programs. These programs involve preschool round-ups of children between 3 and 5 years of age and appropriate alterations in the infant registries referred to above, i.e., deletion or addition of children in this age group, depending on current indications of their need for psychiatric services. This may serve as the basis for an effective school health program, carried out in close collaboration with health and welfare agencies in the community.

Day care and nursery programs with evaluative and remedial components will emphasize the initial manifestations of disturbances in personality formation, as these emerge in the expression of aggressive or sexual feelings. Mental health units in handicapped children's services and chronic disease clinics should be established.

Further integration of preventive efforts should be implemented at every level including psychologically oriented medical examinations and school health programs, with particular emphasis on school health-mental health components, and the availability of psychiatric consultation services.

Total evaluation should be made of children in the sixth and seventh grades to remove the names of those children who no longer require psychiatric care from the infant registries and add the names of others who have developed psychiatric symptoms in the interval since the preschool round-up described above. An early plan should provide for vocational guidance, when indicated.

Adults. If the community's efforts to reduce the incidence of psychiatric illness in adults are to be successful, it is essential that its major social agencies be thoroughly trained in mental health concepts. The ability to identify underlying emotional conflicts, the ability to differentiate between healthy and pathological methods of coping with stress, and a knowledge of consultation techniques are particularly vital. For, in fact, these agencies represent the community's psychiatric antennas, so to speak. More specifically, there is a strong likelihood that individuals in contact with public service agencies, e.g., the department of welfare, public health services and children and family services, vocational and marital counseling agencies, and legal aid societies, may be under considerable stress. Consequently, these organizations are in a unique position to provide counseling services which may prevent more acute psychological crises by helping these individuals to identify and cope with their problems. Concomitantly, the availability of mental health consultation to various groups which are not identified with the mental health professions may prove extremely useful. Thus, social agencies, community social centers, adult education groups, unions and industry-sponsored programs, as well as churches and pastoral groups, may make extensive use of the services of the mental health specialist.

An effective preventive program will evolve from careful investigations of causality, as well as the efficacy of various treatment modalities. And preventive services must continue to reflect the valid findings derived from such investigations. Thus, findings derived from epidemiological research will further our understanding of the nature of the problems of the families we serve, and of the situations which have given rise to these problems. This knowledge, in turn, will facilitate our efforts to develop workable procedures for the integration of preventive psychiatric services into the community "system" and thereby increase their accessibility.

For example, Lawrence E. Hinkle, Jr., and Norman Plummer at Cornell University Medical College concluded from their recent epidemiological studies: "The hazards of illness and accident seem to fall disproportionately on a small minority of the population." These findings have been supported by similar studies throughout the country which have shown that approximately 6 per cent of the families in each of the communities investigated suffered such a multitude of human ills that they absorbed more than 50

per cent of the community's services. Obviously, these multiple problem families must be dealt with by a complex of institutional agencies. Social workers have found, in this connection, that a variety of measures, implemented by agencies of diverse orientation, may have significant preventive value. To illustrate, pediatric hospitals may encourage frequent parental visits to counteract the adverse psychological implications of hospitalization; providing visiting nurse and homemaker services at a time of family crisis may reduce the effects of such crises on children; the efforts of legal agencies to modify adoption laws and procedures to facilitate earlier adoption may prevent the emotional scars frequently associated with prolonged foster home placement; and working with the mothers of children who require intensive psychiatric care at critical points in treatment can help to counteract the feelings of guilt, anxiety, and hostility they may experience in relation to the child, which will inevitably affect their over-all psychological functioning. At the same time, however, these services must be integrated, so that responsibility for the care of the individual and his family is not divided among a great number of social agencies which function independently. As a professional discipline, social work has access to many types of organizations and can often reduce fragmentation by coordinating community resources with needs of the individual.

Nurses are usually most aware of family tensions. Moreover, nursing care is well accepted by individuals under stress. Consultation with mental health specialists can provide the training and confidence which will enable the nurse to intervene effectively, on a preventive level, with individuals. Marital counseling can provide access not only to the emotional problems of the individual partners, but also to the psychological difficulties of the children of the marriage. Counseling, for purposes of crisis prevention, is provided by many family service agencies and community centers, and on an individual basis by physicians and clergymen.

Finally, industry has found that certain policies and procedures and particular attitudes on the part of supervisory and managerial personnel may produce tensions and unnecessary overwhelming anxieties in employees. Mental health education and consultation services for supervisory and medical personnel can facilitate the recognition of emotional disturbance in employees at an early stage, as well as the concurrent development of policies, procedures, and programs dedicated to the promotion of mental health. Typically, such collaborative efforts focus on the components of stressful work situations and the way individuals cope with the anxieties which arise in response to this stress. Thus, mental health consultation services to management can provide a healthier and more gratifying work situation for both management and employees. Consultation services may

also be an effective tool in the rehabilitation of executives and employees who are suffering from the ill effects of environmental stress.

The aged. For senior citizens, once again, primary prevention makes use of its traditional tools of education, consultation, and counseling, based on the premise that intervention through social groups sponsored by community agencies, together with in-service training and consultation to welfare workers, ministers, etc., can prevent breakdown due to the stresses of aging. Frequently, these stresses are aggravated by loneliness; by a society which deemphasizes the role and usefulness of the aged; and by premature, enforced retirement and the lack of leisure time activities. In addition, almost without exception, the aged have suffered multiple object losses through the death of relatives and friends and the maturation and marriage of their children; they must adjust to cumulative role changes; and, finally, they are handicapped by the physical infirmities of old age. Inevitably, these problems will diminish their previous capacity to cope with and master stress. New methods must be developed. Golden Age clubs help with realistic problems (adequate nutrition and housing), and group projects and therapy are appropriate preventive services for the elderly which may be implemented by community centers and social agencies.

Direct Intervention

Direct intervention for prevention in the field of mental health can best be effected by the mental health intervener. The "intervener" is described in some programs as a trained professional who serves the community by intervening directly with those individuals who are considered to represent a high psychiatric risk which, in turn, requires the prior identification of these individuals on some type of registry within the community. Thus, such a registry might include a woman who suffered a postpartum psychosis following the birth of her first child and is pregnant for a second time; a college student who is under considerable academic stress and must make a decision regarding his future vocation; a child who had a particularly stormy infancy and is now faced with the impending birth of a sibling.

In such cases, the mental health intervener, or the representative of a specific mental health agency, may begin to work with the individual or significant family members or friends, to set up a network of resources to prevent breakdown. Preventive efforts may take the form of counseling, education, or early treatment. Obviously, this approach differs from early detection and intervention in cases of demonstrable illness, for it involves predictive judgments which are based solely on the individual's previous maladaptation to stress. Moreover, close community collaboration is required for the identification of this potential patient population. Presumably, teachers,

policemen, attorneys, etc., would refer such an individual to an intervening agency or provide the intervener with information which would permit him to approach those in need of his services directly. In any event, this is a new concept which requires a highly sophisticated network of communication.

It also requires a benignly aggressive approach on the part of the intervener who must seek out and deal with individuals in culturally and economically deprived groups who are frequently poorly motivated for treatment. Yet, a number of sociological and epidemiological studies have established conclusively that there is a higher incidence of suicide, delinquency, and mental illness in socially disorganized areas. One possible explanation for this finding is that individuals who live in disorganized communities and are unable to develop effective living techniques are unaware of the care-taking and helping agencies within their environment. Consequently, mental health and social agencies must themselves seek out and approach these individuals to provide the intervening help which will diminish their emotional and social disorders.

46.2 SECONDARY PREVENTION

IRVING N. BERLIN, M.D.

Secondary prevention may be defined as the early identification of disease and disorder, which, of course, is a prerequisite for prompt treatment. This section will attempt to explore those measures which are currently believed to facilitate such identification. For purposes of this discussion, the term "disease" is used to refer to pathophysiological conditions which arise from "impersonal" processes. In contrast, the term "disorder" is used to connote those disturbances of function which result from intra- and interpersonal conflicts. As pointed out elsewhere in this volume, diseases and disorders are frequently

both coexistent and interrelated, but their differentiation, particularly in children, is often important.

Infancy and Early Childhood

Psychophysiological disturbances of infancy and early childhood present unique opportunities for early identification of later more intractable psychological disorders and irreversible pathophysiology. Several authors, Stewart et al. and Escalona and Leitch among them, have demonstrated that sleep and feeding disorders and the colic of infancy may be a prelude to more severe disturbance in later life. The various factors which combine to produce chronic disturbances in sleep and feeding patterns and colicky crying in infancy may include the seeds of a seriously impaired mother-infant relationship. And this variable may emerge with greater clarity at a later stage of development as the crucial etiological factor in the genesis of autistic behavior, severe obsessive-compulsive or phobic symptoms, or marked physiological dysfunction.

In light of these findings, a number of contributors to Caplan's *Prevention of Mental Disorders in Children* have suggested that the diagnostic significance of these early symptoms, in terms of their relationship to future psychological or physiological dysfunction, can best be evaluated by close observation of the mother-child interaction. Thus, several investigators have recommended that the community mental health worker establish a relationship with the mother which will permit a clear assessment of her reactions to the pregnancy and the subsequent presence of the infant; the extent to which the care of the infant appears to drain her energy; the effect of the presence of the infant on her relationship with her husband; and, finally, evidence of underlying postpartum depression. The accounts by Levy and Call of their experiences in a well baby clinic demonstrate conclusively that psychotherapeutic intervention, where indicated, can be very effective at this stage. Such psychotherapeutic efforts may be relatively unsophisticated. For example, the worker's willingness to listen to the mother, his empathy and supportive concern, may play a significant role in the alleviation of the baby's disturbance. On the other hand, the worker may attack the problem directly and simply inform the mother that increased cuddling, tender handling, and playful stimulation may reduce the baby's disturbance. He may even demonstrate these techniques. In either event, the approach is task-oriented; it does not focus on maternal psychopathology and deep interpretation; and in this setting, with this patient population, it has proven most effective.

Psychophysiological disorders. The etiology and the specific mechanisms which underlie psychophysiological disorders in infancy and childhood are dis-

cussed elsewhere in this volume. This section is restricted to discussion of their early recognition and prompt treatment. The occurrence of eczema, asthma, gastrointestinal problems, and other psychophysiological disorders can frequently be related to the arousal of anxiety in the child. And again, most frequently, such anxiety is precipitated by an acute situational problem within the family or alterations or strains in the child-parent relationship which, in fact, are due to increased parental tensions and conflicts. Several contributors to the symposium on the *Prevention of Mental Disorders in Children*, cited earlier, contend that once the emotional aspects of psychophysiological disorders have been delineated and differentiated from increased exposure to antigens and other physiological stress, it is possible to reconstruct the history of the psychophysiological disorder and the nature of the stress which precipitated it. Once these data are available, they may serve to underscore the need for prompt psychological treatment, as a possible means of preventing irreversible tissue changes. It must be emphasized, however, that clinical experience has shown the treatment of psychophysiological disorders may prove ineffective if it is restricted to the emotional state of the child and the parent-child relationship. Rather, equally vigorous measures must be initiated for the medical treatment of the disordered physiology, including attention to allergens and desensitization, etc. In other words, all the aspects of the disorder must be attended to.

Equally essential for effective early treatment is a searching examination of the parents' anxieties regarding the child's illness and, more specifically, their parental responsibility to take whatever action may be necessary to alleviate the child's discomfort. For example, the failure of parents to administer medication promptly at the first signs of an asthmatic attack and their subsequent intense guilt when the full blown attack requires heroic measures may be considered from several perspectives. However, the efforts of the community mental health worker will be most effective if his attention is directed to examination of the parents' indecisiveness. Obviously, helping the parents to act promptly at the first sign of an exacerbation of the disorder is an important preventive measure. The child's well-being is the primary consideration. Thus, whatever the underlying causes of the parents' indecisiveness, whether it is caused by their conflicts with each other or disturbances in their relationship with the child, they must learn to put these aside, so to speak, to act on the child's behalf and thereby reduce the frequency and severity of episodes of asthma, eczema, cyclic vomiting, diarrhea, diabetic coma, and insulin reactions, etc. Often, detailed instructions about the action to be taken at the onset of the first symptoms, together with strong emphasis on the importance of prompt intervention, helps parents to recognize their

failure to note the early signs of onset of an episode, although they are well known. When the parent learns to behave appropriately early in the course of the child's psychophysiological disorder, he may function as a more effective parent in other situations, as well. In addition, his more constructive attitudes toward the child may correct some of the distortions in the parent-child relationship and even reduce his conflicts with the other parent.

Finally, mention should be made of the fact that the mental health workers on the staff of child psychiatric and pediatric centers which concentrate on the treatment of psychosomatic disorders have been impressed by the fact that evidence of a possible etiological role of psychological factors in the onset of the first few episodes of a psychophysiological disorder is frequently dismissed as only accidental or incidental. And, since the implications of disordered child-parent relationships are not recognized, they are not considered to require evaluation and careful investigation.

Psychological disorders

Neurotic disorders of infancy and early childhood. Severe neurotic disturbances are the emotional disorders encountered most frequently in infancy and early childhood. Furthermore, their early treatment and identification may play a crucial role in the prevention of impaired function in later years. The etiology, symptomatology, psychodynamics, and treatment of these syndromes are discussed in detail elsewhere in this volume. Above all, the early recognition of a neurotic disorder depends on the awareness of psychiatrists, pediatricians, public health nurses, etc., that the persistence of any aberrant behavior which clearly impairs the living and learning process of an infant or young child has potentially serious import. Thus, the problems which are commonly associated with sleeping, eating, crying, inappropriate fear reactions, head banging, head rolling, and withdrawal become important when they persist and begin to interfere with the child's development. Obstacles to the child's ability to fulfill his developmental tasks of exploring his environment, forming relationships, learning to his capacity, and adapting to family and societal norms merit prompt attention. Again, if, because of his atypical behavior, the child requires an inordinate amount of time and attention from the parents or parent substitutes, investigation is in order.

As mentioned earlier, the etiology of neurotic disorders in childhood has been discussed elsewhere in this volume. However, a brief example of the role of parental attitudes in precipitating such disorders, viewed from the perspective of community psychiatry, is relevant in this context. Parents' concerns about bowel and bladder training may, on the one hand, simply indicate their desire to be rid of the messiness and trouble which is a concomitant of

child care. But, on the other hand, when such excessive concerns are coupled with a picture of chronic constipation in the child, bowel retention, and fecal dribbling and smearing, they may have more serious implications; at the least, careful observation is indicated, and prompt therapeutic work with the child and his parents is highly desirable. Most often bowel difficulties in the child reflect the anxieties of young, inexperienced parents who are reluctant to exercise their parental prerogatives by being explicit in their expectations and firm in their handling of bowel training. Often, these parents are immature and irresponsible in many areas and need to be helped to accept the adult responsibilities for which their own childhood and adolescence has ill prepared them. In other instances, the same symptoms result from severe and hostile rejection of the child by very emotionally disturbed parents.

Excessive, irrational fears; obsessive-compulsive behavior; and demands for invariable sameness of routine, with panic when there is even a minor change in this routine, are indicative of the presence of potentially serious emotional problems. The child's fears of the noise of airplane engines, flushing toilets, elevators, sudden loud noises, and strange faces, at which times he cannot be reassured or comforted by the parent, may indicate the presence of similar fears and massive anxieties in the parent, which have been transmitted to the child, or they may represent a defensive reaction on the part of the child to his traumatic relationships with adults.

In the 2- to 4-year-old child, the failure to develop verbal skills and the inability to communicate on a verbal level may be the first indication of emotional conflict. Verbal communication is, of course, the essence of human interaction, and children usually learn to speak at this age. Therefore, developmental deviations in this area may reflect interpersonal problems or organic impairment. In any event, this problem requires prompt investigation, correct diagnosis, and appropriate remedial measures, to avoid the more serious sequelae of communication difficulties.

Psychoses of childhood. The reader is referred to the detailed discussion of autism and other childhood psychoses elsewhere in this volume. This section is restricted to delineation of those symptoms which are believed to be diagnostically significant. There is general agreement that the treatment of these serious disorders must be undertaken early and that intensive and all encompassing therapeutic efforts are required. Warning signals of the possible presence of a psychotic process include the child's withdrawal into a world of his own, with concurrent isolation from adults and peers; self-gratification through continuous sensual activities of rocking, twirling, and masturbation; failure to learn to speak, or the loss of speech after it has been learned, or the use of speech for idiosyncratic purposes, rather than com-

munication; sleep disturbances and severe feeding problems; ritualistic obsessive behavior which interferes with play and learning; hostile, aggressive, assaultive behavior, without apparent provocation; and many other symptoms.

Such children may require treatment in a residential setting; at the least, treatment should be provided within the therapeutic milieu of a day care center or preschool program. Moreover, treatment of the child should be coupled with treatment of his parents. Apart from the fact that the parents of such a child frequently present serious intrapsychic problems, on a more concrete level, they need help if they are to be able to live with and manage a psychotic child. In this connection, it has been the experience of a number of treatment centers that parents may learn a great deal by watching "experts" work with their child and handle his deviant behavior. At the same time, their own efforts to help the child, under the guidance and supervision of skilled personnel, may help them to function more effectively in this very difficult role.

Mental retardation. The mentally retarded child whose behavior is very disturbed—and disturbing—and who functions at a level below his limited capacities requires the same treatment measures prescribed above for the psychotic child. Here, too, the parents require considerable support and help with their feelings of guilt, as well as assistance in their efforts to manage their child at home. In these instances, actual task-oriented demonstration and appropriate follow-up have proven helpful in reducing disturbances in the behavior of the mentally retarded child and improving his functioning.

The School Age Child

Signs of emotional disturbance. Much of what was said earlier with regard to the early diagnosis and treatment of emotional problems in infancy and early childhood applies to the school age child as well. However, there are important differences in diagnostic criteria. At this age, the child's primary developmental tasks are learning and the acquisition of knowledge and of specific educational skills in school; concomitantly, serious interferences with learning are of real concern.

Most frequently, such learning difficulties are associated with the aggressive, the hyperactive, the withdrawn schizoid, and the sullenly apathetic child. But when a child presents such problems, diagnostic efforts must be both extensive and intensive, for their actual cause may not be readily apparent. To illustrate, a withdrawn, schizoid, 8-year-old girl was frightened of her classmates, could not retain information, and was unable to master even the simplest aspects of reading. On superficial examination, the presence of psychopathology seemed self-evident. In fact, however, this child had a serious thyroid deficiency. After she had received proper treatment,

she became an alert, interested student, whose serious learning impediment had magically disappeared. Similarly, the hyperaggressive child may be organically impaired, or he may have a neurotic behavior problem. And there is a third possibility: he may be a psychosocially deprived child, whose poor preparation for learning and consequent history of school failures have resulted in frustrated, angry behavior.

Treatment. Obviously, the treatment of the child must be based on etiological factors. In addition, however, parents must be helped to recognize their responsibility toward such a child. If remedial efforts are to be successful, parental cooperation is essential, and this will often include their willingness to accept specific suggestions about the handling of the child. Finally, the worker's efforts with child and parents must be of sufficient duration; that is, the therapeutic relationship must continue beyond first indications of an alteration in the child's behavioral and learning problems until their final amelioration.

Often, aggressive, antisocial behavior in school is reduced once the child is no longer frustrated by his inability to learn. A number of educational measures may serve to increase the child's learning capacity. For example, the use of small classes, so that each child receives more individual attention; the use of a wide variety of sensory and motor modalities in the teaching program; and, in general, increased stimulation to broaden the child's cultural horizons and interests have proven effective in this connection.

The foster child. Early diagnosis and treatment of emotional disturbance and concurrent learning difficulties in foster children and in children in institutional settings has received a good deal of attention in recent years. These children frequently manifest apathy and indifference, on the one hand, and an impulsive, conscienceless drive for gratification on the other. Either symptom complex, or both, should alert educators, physicians, and psychiatrists not only to the need for individual treatment, but for a variety of restitutive experiences with groups of children, and with adults who care for them as well. Arsenian has pointed out that, whatever their age, these children require the kind of experience provided in the preschool program for socially and culturally deprived youngsters. This program emphasizes concern for the well-being of the individual child; as such, the program provides a wide variety of stimuli, and each child receives constant, consistent help until he experiences satisfaction in the learning process. Arsenian's study of a group of children and young adolescents from inadequate foster homes presents conclusive evidence of the efficacy of this approach.

The Adolescent

Signs of emotional disturbance. The emotional turbulence which characterizes adolescence presents

special difficulties in early case finding and treatment. The ever present problem is differential diagnosis. The worker must be able to discriminate between an actual disorder requiring treatment and an exacerbation of "normal" adolescent turmoil. The treatment of adolescents may also present special difficulties. Thus, the diagnosis and treatment of emotional problems in this patient category merit careful consideration and are discussed at length elsewhere in this volume.

Although this may be true of the younger child as well, in adolescence, sudden changes in the usual behavioral and learning patterns are particularly significant and should be investigated. Intercurrent family stress often results in fairly rapid alterations in behavior and learning. Thus, when the good student, one without prior behavioral difficulties, begins to do poor work or act up in class; when the aggressive, teasing student suddenly becomes quiet and withdrawn, some inquiry is in order. Often, such abrupt changes in behavior are initiated by death in the family, divorce or separation of parents, birth of a sibling, father's unemployment, or the serious illness of a family member. In any event, early recognition of the behavioral change and efforts to find out its cause may be important for the prevention of future disorder. The youngster or adolescent who finds someone he can tell his troubles to, who may even help him when he feels alone and helpless, may quickly recover his equilibrium. When a helping adult is not available in periods of crisis, the disturbed behavior may continue. The feelings of helplessness and aloneness may then give rise to a variety of inappropriate efforts to restore equilibrium, which, in fact, are intended to "advertise" the adolescent's distress. If they persist, unrelieved, over a period of time, these deviations may finally become "set" as enduring maladaptive behavior.

A 15-year-old boy who was usually very truculent and defiant suddenly became quiet and depressed. His teacher's inquiries led to a surly "mind your own business." However, his involvement in several gang fights, which represented a new activity for him, led to his counselor's persistent efforts to discuss his sudden behavioral changes. After several weeks, the boy told the counselor, with much emotion, of his mother's death, his father's unabated drinking, and his concern for his younger siblings who were turning to him for guidance, help, and many parental decisions, for which he felt he was unqualified. With the counselor's help, homemaker services were provided, there were several conferences with the father, and the boy was persuaded to continue his counseling interviews. His fighting and depression abated promptly. As he continued to be aware of the counselor's support, he also became less truculent and difficult in class and more interested in learning.

Thus, in this case, a family crisis which impinged on preexisting psychopathology provided an opportunity for early intervention and prevention of a potentially serious disturbance. In addition, this crisis served as a therapeutic "springboard," which furthered the boy's total integration. In this sense, the crisis states of adolescence provide a variety of thera-

peutic opportunities. For the patient is helped not only to cope with an immediate crisis, but to resolve previously troublesome and maladaptive behavior patterns.

The adolescent's overwhelming sexual urges, his search for identity, and his ambivalent desire for closeness and independence make for potential violence. Some authors have stressed the fact that the antisocial behavior which is so common during this stage of development may be a defense against depression. Actually, once again, the first recognizable signs of such depression often take the form of sudden changes in social behavior. Thus, signs of imminent decompensation may be manifested by shifts from socializing with "well behaved" old friends and a good deal of athletic activity, to running with a delinquent gang; from a tendency toward isolation, to very gregarious, almost manic social activities; or, conversely, from a full social life, to complete isolation and intense preoccupation with one activity. Studies of suicide in adolescence emphasize the importance of these mood swings as indicative of emotional disturbance. Such sudden alterations of behavior may also indicate an incipient schizophrenic breakthrough, especially if the patient is excessively preoccupied with religion, or if he identifies with unpopular political or socioeconomic causes, to the degree that his activities include regular attendance at the meetings of lunatic fringe groups. However, the implications of a radical alteration in an established pattern of behavior may be more subtle. For example, one adolescent, who had previously demonstrated a complete lack of concern with science, suddenly developed an intense interest in chemistry. Although this new interest seemed commendable at first glance, investigation disclosed that the youngster was convinced that his chemistry set held the answers to the nature of living matter; once he had these answers, he would be able to save civilization.

Of singular importance is a sudden change in adolescents from conforming behavior (which includes a normal amount of truculence, argumentativeness, and loss of temper), to outbursts of uncontrollable and violent rage. In several instances, such sudden shifts have preceded violent psychotic episodes. In one case, where the sudden change to uncontrolled violence was detected early and led to hospitalization, it became apparent that the patient was potentially capable of murderous assault on his father. Retrospective studies of adolescents who murdered their parents have highlighted these sudden behavior and mood swings.

With the blossoming of secondary sexual characteristics, young girls who had little parental closeness and warmth in early childhood and have few friends or social contacts acquire an important weapon which may facilitate their search for closeness. Specifically, their provocative sexual behavior serves to give them the feeling of being wanted, albeit by

boys, and solely for sexual activity. Ideally, the school faculty will be alert to such unconscious attitudes and their expression through radical changes in behavior. Typical danger signals, such as an abrupt change in previous levels of scholastic performance and a shift in the adolescent's previous eagerness for the good opinions of favorite teachers, may be the forerunners of sexual acting out and pregnancy. One school has organized special groups for these youngsters, under the supervision of skilled group leaders. The members of these groups do achieve the closeness they yearn for, with both their peers and the group leader; this closeness derives from their joint efforts to explore and resolve their common problems. The community has benefited from this innovation as well, for there has been a conspicuous reduction in the number of unwed mothers who attend this high school.

Delinquent behavior. One cannot leave the problems of adolescence and their implications for secondary prevention, without brief reference to antisocial, delinquent behavior. Antisocial, delinquent behavior is usually attributed to sociocultural factors, i.e., to slum environments and the distorted values of the subcultures such environments breed. Clinical experience has shown, however, that this type of deviant behavior cannot always be correlated with socioeconomic deprivation. The delinquent behavior of an "advantaged" youngster may stem from mounting intrafamilial tensions, in which event prompt intervention with the parents, as well as the delinquent child, is essential. Some authors consider family therapy the treatment of choice in such cases. The work of the Children's Hospital Child Guidance Clinic in San Francisco is notable in this regard. The results of forced, i.e., court-ordered, family therapy in other settings have also been promising. In fact, prompt psychiatric referral by the courts and the subsequent collaboration of officers of the court and psychiatrists or members of ancillary professions are vital to the prevention of future antisocial, delinquent behavior. Ideally, however, the prevention of antisocial behavior in adolescence will begin with the school age child. According to Bower and Glueck and Glueck, the data collected by several school systems in the service of secondary prevention clearly indicate that impulsive, aggressive behavior, learning blocks, and a refusal to conform to school and classroom rules and regulations noted in the first three grades of school are excellent predictors of future antisocial, delinquent behavior in junior and senior high school. These findings underscore the importance of early diagnosis of impulsive character disorder in the child and/or disturbed family relationships; efforts to work with the child and his family at this point may prevent further disorder, intractable delinquency, and criminal behavior.

The pathological antisocial behavior described above must be differentiated from occasional anti-

social escapades and assertiveness. Joy riding in the family car may be distressing for parents and the community. However, it does not necessarily reflect an underlying emotional disturbance. That is, these occasional acts of rebellion do not usually become a way of life, and the major source of satisfaction and gratification.

Finally, special reference should be made to the type of antisocial behavior which has a sudden onset and then becomes increasingly serious, in which the adolescent deliberately leaves clues establishing his guilt, or performs acts of flagrant provocation. These youngsters want and desperately need to be stopped by their parents or by the authorities. In several such cases, this behavior was clearly part of a schizophrenic process which yielded to prompt hospitalization, therapy for the patient, and family therapy. Treatment focused on helping all the family members to understand why the repeated hints and clues given by the adolescent were not "picked up" and acted on by the parents or older siblings and also the nature of disturbances in family communication which prevented the adolescent from expressing his problems and needs directly.

Secondary Prevention in Adult Life

Signs of psychological decompensation. Evidence of psychological decompensation in the adult, which may result in severe depression, suicide, or psychosis, often emerges most clearly in association with life crises and concomitant changes in established patterns of behavior. As pointed out elsewhere in this chapter, parenthood may present one such crisis, especially if an unwanted child arrives at a critical point in the life of a family. In any event, parenthood will inevitably require some changes in the life style of the father as well as the mother. In addition, job changes, a move from one community to another, or the loss of parents, spouse, or other supportive adults may prove to be crucial events which lead to decompensation.

Awareness of the signs of incipient decompensation permits intervention, if they are understood and heeded. Therefore, such awareness is of crucial importance for the family physician, as well as the psychiatrist. Similar signs have been described as precursors of psychophysiological disorders, specifically asthma, peptic ulcer, arthritis, and ulcerative colitis. In general, these signs include acute dissatisfaction with one's work and way of life and the deterioration of integrative relationships. While they may appear similar at first glance, these manifestations are very different from the chronic griping which for many individuals constitutes a means of adapting to or coping with difficult or unpleasant situations. The signs of dissatisfaction which have serious diagnostic implications carry with them an underlying feeling of hopelessness with regard to the

individual's ability to solve his problems and the conviction that the future holds no promise.

Some authors have noted, in particular, inability of such adults to gain relief from their overwhelming feelings of depression and dissatisfaction through the activities or forms of recreation which they had found most enjoyable in the past. Repeated statements, over a prolonged period of time, that everything is flat, tasteless, and without zest are typical of this patient population. Recurrent, irreducible feelings of guilt about someone's death or illness or chronic anger and hatred toward a particular person in the family or work environment also carry with them the possibility of incipient and serious illness, especially when these feelings are related to crises and changes in life patterns. Some investigators contend that when psychological decompensation is suspected, it is better to err in the direction of unnecessary investigation and involvement of family members in treatment, than to wait in the hope that such feelings will pass. Many authors have also pointed out, in this connection, that an abrupt change in the patient's behavior, whereby pessimism and dissatisfaction give way to sudden optimism and gaiety, is not cause for therapeutic optimism but may, in fact, be a sign of impending suicide or a break with reality.

Psychological hazards of the climacteric. Obviously, the climacteric carries such hazards for both men and women. The feelings that one's life work and productivity are at an end, that one is no longer needed or wanted, attractive or desirable, are all potential precipitating factors of decompensation. The depression which accompanies the climacteric is a common phenomenon in women and has been described at length in the literature. A number of investigators have also made specific recommendations as to how women in this age group can be helped to feel useful and important after their children are grown. Much less attention has been paid to the effect of the climacteric on men; yet they have similar reactions, i.e., that their productive years are drawing to an end. The depression evoked by such feelings, preoccupation with somatic complaints, and paranoid feelings toward younger friends and co-workers need to be attended to promptly, for they are possible precursors of serious depression.

Many incompatible married couples are held together solely by their joint efforts to raise their children. Once the children are grown, some of these men and women are tortured by the feeling that they have sacrificed their own need for closeness, tenderness, and companionship in vain, for now their lives are without purpose. Such feelings may lead to acute decompensation. Severe depression, schizophrenic breaks, and, in several cases, manic episodes, have occurred at this juncture in the lives of both women and men in their middle forties. In these patients the preexisting psychopathology which was previously controlled or

sublimated in work and in the service of the family has now erupted with overwhelming effect. Retrospective evaluation of these patients has also disclosed that here, too, there were signs of incipient serious decompensation in the form of acute and continued dissatisfaction with everything and everyone in the environment. Sometimes, the patient sought to escape from reality by grandiose, and completely unrealistic, plans for the future.

After reduction of the acute process, clinical reports indicate that the use of combined individual and conjoint therapy is the most effective therapeutic approach in these cases. When it has been successful, therapy has focused on the realities of the present situation and marital relationship. This often permits each partner to verbalize, for the first time, what he (or she) wants and needs from the other. With the help of the therapist, they can proceed from this point to consideration of how these needs and desires can be met in the existing relationship.

Secondary prevention of psychophysiological disorders in adults. The investigations of Rosenman and Friedman of coronary occlusion have important implications for prevention and early intervention in psychophysiological disorders. These authors postulated, on the basis of their research findings, that those individuals who are driven to meet schedules, who are constantly pushed by their need to be perfect and above criticism, have a much higher incidence of coronary arteriosclerosis and coronary heart disease than others who do not manifest these characteristics. These individuals are unable to relax, to use recreation to renew themselves. Of particular interest are those studies which hypothesize that coronary occlusion may occur when an individual is under intense competitive pressures, when these feelings have been preceded by self-doubt, i.e., the conviction that he is no longer able to keep up with younger, brighter men, that he has lost his drive and alertness. He may be so drained by the pressure of competition that he is quite unable to marshal and use his accumulated knowledge, experience, and wisdom effectively. Consequently, he feels compelled to rely on increased output, to "perform," and to be well thought of. These signs become particularly significant when they follow major job changes or changes in residence. Thus, these investigations have important preventive implications for business and industry, in that they facilitate the more efficient use of manpower. In addition, of course, the psychiatrist's early recognition of the signs of incipient psychophysiological disorder and his prompt intervention may help these individuals to retool, so to speak, so that they may make more effective use of their capabilities and experience.

Secondary Prevention and the Elderly

Signs of psychological decompensation. With the passage of time, the senior citizen in our highly

industrialized technical society has grown progressively less productive and useful. Even in the sciences it is felt that most of the important discoveries will be made by scientists before they reach the age of 40. Thus, retirement and old age carry with them the psychological burden of uselessness; in addition, however, the elderly are frequently forced to enter new areas of work and recreation, in which they have had no prior training or experience. This sense of uselessness, in combination with the inability to derive satisfaction from life and a consequent lack of purpose, is considered by many workers to represent a crucial precipitating factor in the senile psychoses and in less serious symptoms, such as overreaction to somatic symptoms which, in fact, are neither serious nor disabling, and a preoccupation with the past which often precludes forming new relationships and adapting to a new way of life.

Secondary prevention and early intervention into the decompensating illnesses of old age seem to center around awareness of this frequent combination of events. The obvious goal of such intervention is to help the elderly to feel wanted, useful, and important to their families and the community. In light of this therapeutic prescription, it becomes easier to understand why the communities which have been established for the elderly represent a glaring failure of our efforts on their behalf. The senior citizen who resides in such a community is surrounded by others with whom he may have nothing in common apart from old age, ill health, and unhappiness. The fact that only recreational activities are provided to give his day purpose further underscores the inadequacy of this program. In marked contrast are those programs where the particular skills and talents, often latent, of the aged are mobilized and utilized by skilled group workers, to give the elderly a sense of purpose and worth. Perhaps the most encouraging examples of this approach are the programs which have been established in several homes for the aged where each newcomer is involved in a variety of community activities by a "reception committee" in the home. Because the members of the committee have lived through experiences similar to those the newcomer must now face, they can verbalize their awareness of his feelings. Through constant attention and preceptorship, they can then help the newcomer to find activities in the community which, for him, carry status and a sense of contribution. The members of the reception committee, in turn, feel that through their activities they have made a vital contribution to the community. Furthermore, in their efforts to help newcomers explore possible areas of interest, they, themselves, become involved in activities which are an unsuspected source of satisfaction. The costume designs of a retired insurance salesman for the twice-yearly drama productions at one home have been so good that the directors of some little theatre groups have come to him for help and advice. In another

home for the aged, for the most part, only residents with more serious complaints report at sick call; hypochondriasis is infrequent because most of these elderly people are reluctant to miss their daily activities.

Feelings of loneliness and isolation represent the most serious cause of acute decompensation. In terminal illness, the old person is frequently left alone and provided with impersonal nursing care, so that there is no sustaining and comforting concern for him as an individual during these painful and frightening hours and days. One of the most important committees in the homes for the aged described above, whose members are chosen for their stability and capacity to express their compassion and support, is the committee that visits the sick. In addition, the nursing staff has learned enough about each individual patient under their care to make him feel that he is really the object of their concern. The fact that the surgical staff does not hesitate to nail a broken hip in an 80-year-old man or woman, or to do other major surgery which in other institutions and hospitals is frequently fatal, is further evidence of the degree to which efforts are made to provide both physical and emotional comfort and support for these old people.

This discussion attempted to point up some of the vital ingredients of secondary prevention. It must be emphasized, above all, that early awareness and diagnosis of emotional disturbance and the efforts at early intervention express an implicit concern with the well-being of the individual of any age and a hopeful attitude that appropriate treatment and restitutive efforts will help to restore his equilibrium or enable him to develop more effective modes of adaptation in the future.

Suggested Cross References

For more detailed information regarding the diagnosis, clinical features, etiology, and treatment of the disorders mentioned in this section see Chapters 42 and 41, which deal with the psychotic, neurotic, and psychophysiological disorders of childhood, and Area F, which deals with these psychiatric disorders in adults. Primary and tertiary prevention of psychiatric disorders are discussed in Sections 46.1 and 46.3.

46.3 TERTIARY PREVENTION

ALFRED M. FREEDMAN, M.D.

Definition

By definition, tertiary prevention, as one aspect of the application of psychiatric principles within the larger setting of the community, addresses itself to the task of reducing the rate of defective functioning caused by mental disorder. Within this frame of reference, however, tertiary prevention would be considered to encompass all of psychiatry, or, more accurately, the life process itself, for the mental health status of a community at any given point will affect—and be affected by—its child-rearing practices, social attitudes, and every phase of its social and psychological life. For obvious reasons, this broad definition precludes precise discussion of the principles of tertiary prevention; consequently, the term is generally used in a more restricted sense. Gerald Caplan, for example, has limited the goal of tertiary prevention to “reducing the residual defect... which continues after the mental disorder has ended,” and has further defined “residual defect” as the individual’s “lowered capacity to contribute to the occupational and social life of the community.”

Implicit in this restricted definition is the crucial role of rehabilitation services which seek to enable the ex-patient to function with maximum effectiveness as promptly as possible following hospital dis-

charge. Since these services are particularly important immediately following hospitalization (i.e., during the "after-care" period), technically, they would be considered a continuation of therapy. However, it is the rehabilitative aspect that gives meaning to any therapeutic after-care service, whether it is provided in an out-patient clinic, a day or night hospital, or any other setting.

This section will confine itself to a discussion of tertiary prevention in this limited sense and, as such, will focus on issues pertaining to the rehabilitation of individuals who have recovered from the acute phase of their mental illness. At the same time, it is, of course, readily apparent that some of the elements which determine level of functioning after the cessation of a mental disorder may long antedate the actual onset of the disorder and have their origins in the individual's early psychosocial development. There is a tendency among some workers, based on such considerations, to disparage tertiary prevention and emphasize primary prevention instead. Certainly, the essential value of primary prevention in terms of the welfare of the individual, as well as the community, cannot be disputed. Nor is there any doubt that our efforts should be directed—first and foremost—to the implementation of the principles of primary prevention. However, this in no way diminishes the importance of tertiary prevention. While primary prevention may remain the principal focus of our activities in the field of community psychiatry, our efforts in the area of tertiary prevention must not lag: we must continue to apply present day knowledge, which is considerable, in order to provide services which will further reduce the rate of residual defect following acute mental illness. There is no question of the validity of Caplan's comments in this connection. He has pointed out that our knowledge of rehabilitation techniques for psychiatric patients has advanced considerably. Yet, "in this country we are only in the earliest stages of utilizing this knowledge and planning programs for that large-scale reduction of residual defects which is the essential ingredient of tertiary prevention." It has become increasingly evident that we cannot hope to achieve this goal or reduce the hard core of chronic patients who continue to deplete the community's resources unless we establish rehabilitation and after-care services of the highest quality.

Guiding Principles

If it is to be successful, a tertiary prevention program must fulfill certain basic prerequisites. First, such a program must, above all, reflect the central underlying proposition of tertiary prevention, namely, that planning for rehabilitation must begin with the onset of mental illness. Furthermore, thereafter, it must be inextricably intertwined with every facet of patient care throughout the diagnosis, treatment, and after-care.

Second, a tertiary prevention program must strive to ensure continuity of responsibility for patient care. More specifically, provision must be made for the care of the mentally ill patient at every stage of his illness—not only during the period of hospitalization, but during the transitional period immediately following hospitalization, and even after the patient has resumed his former role in the community. It is generally recognized that no matter how effective an in-patient treatment program may be, it is unlikely that the patient will be able to maintain his therapeutic gains after discharge from the hospital unless adequate follow-up services are provided. Yet, all too frequently, at various stages in the course of his illness the psychiatric patient is enrolled in different treatment programs sponsored by different agencies which make little attempt to coordinate their efforts to fulfill his individual needs.

Third, the effectiveness of a tertiary prevention program will depend, in large measure, on whether adequate precautions have been taken to guard against the "desocialization" of the hospitalized patient. In fact, the alienation which is a frequent concomitant of hospitalization has, quite justifiably, become an important focus of psychiatric concern within the past 2 decades. All too often the patient returns to the community after he has been discharged from the hospital only to discover that in his absence his family, as well as the community, has "closed ranks" against him. The consequences in terms of the patient's future progress are self-evident. In the past 20 years, too, various techniques and principles have been developed which seek to avoid—or, at least minimize—the "desocialization" which is an intrinsic element of all mental illness.

One such "remedy" immediately presents itself: "desocialization" can be avoided and rehabilitation facilitated by keeping the patient out of the hospital. This is not always possible, of course. However, through the development of community services (e.g., walk-in clinics, out-patient treatment facilities, and social work agencies), that is, the establishment of effective secondary prevention programs, the need for hospitalization can be eliminated completely or the actual period of hospitalization shortened significantly, in a large number of cases.

For another segment of the patient population, the home care programs which have been initiated by several hospitals represent a possible alternative to hospitalization. These programs provide for the treatment of psychiatric patients in their homes by ancillary personnel—e.g., public health nurses, occupational therapists, clinical psychologists, and social workers—under the supervision of the hospital psychiatrist. Apart from its value in reducing the sequelae of alienation, the home care program has important "administrative" implications. For one, a larger number of hospital beds become available for those patients whose illnesses are more severe. Sec-

only, it presents one possible solution to the serious problems posed by the current shortage of professional personnel in state institutions and general hospitals alike, which has become a matter of increasing concern. When the hospital psychiatrist is able to delegate some share of his responsibility for patient care to members of the ancillary professions, his services can be used to greater advantage.

Other innovations developed within the past 20 years are described in greater detail below as "rehabilitation resources." Ex-patient clubs, halfway houses, etc. serve not only to facilitate the rehabilitation of the psychiatric patient, but also to help prevent his rehospitalization. Similarly, the use of day hospitals, night hospitals, etc. may obviate the need for full time hospitalization and thus enable the patient to maintain his ties with the community.

Various techniques are employed to foster socialization in those patients for whom there is no alternative to full time hospitalization. These include ward meetings and discussions, group recreational activities, etc. In brief, the principle of the therapeutic community is generally recognized as a valid approach to the treatment of the hospitalized psychiatric patient, insofar as it reduces the residual defect which is an inevitable consequence of the patient's separation from society.

Finally, two well established principles central to the philosophy of community psychiatry must be mentioned in any discussion of procedures which seek to counteract the effects of "desocialization." Both propositions have met with increasing acceptance over the years, so that today they are applied almost automatically. The first of these refers to treatment of the psychiatric patient⁶ within the community, i.e., in the general hospital, whenever feasible (as opposed to his admission to a mental institution which may be many miles from his home and family).⁶ The second related proposition is concerned with the advantages of short term hospitalization (and subsequent treatment on an out-patient basis), as opposed to long term hospitalization. Clearly, the application of these fundamental principles is basic to any program which is designed to circumvent the ill effects of alienation.

Rehabilitation Services

Definition. In the strict sense, the purpose of rehabilitation services is to help the psychiatrically handicapped individual to achieve as high a level of adjustment as is possible on his return to the community following treatment. It is understood, however, that the level of functioning in any given case may be limited by the residual disability which persists despite all efforts. Accordingly, Bertram Black has extended this traditional concept of rehabilitation to include educational procedures and various forms of environmental intervention which are di-

rected primarily toward those individuals who, because their psychiatric disability had its onset early in life or was constitutional or genic in origin, had not had an opportunity to function normally in the community previously. Black has described such efforts, appropriately, as "habilitation" services.

History. With the exception of a few isolated efforts, for all practical purposes, no formal, community-based psychiatric rehabilitation programs had been established in the United States prior to 1950. Black has listed the rehabilitation resources which have been established in the United States in the years since in chronological order as follows: (1) ex-patient clubs; (2) day hospitals, night hospitals, and week-end hospitals; (3) foster home care, halfway houses; (4) rehabilitation services for the world of work; and (5) rehabilitation centers.

Ex-patient clubs. The great majority of the ex-patient clubs in existence today are sponsored by the administrative staff of the mental hospital or clinic with which they are affiliated. However, the original impetus for the organization of this type of facility came from the ex-patients themselves. While their leaders were recruited from their own membership rosters initially, today, to an increasing extent, they are administered by professionals from various disciplines who are paid for their services.

The primary objective of the ex-patient club is to help the ex-patient to learn—or relearn—social skills. To this end, it provides a permissive, informal ambience, in which socialization is encouraged through organized group activity and individual relationships as well. Those in ex-patient clubs engage in a variety of recreational activities, such as dances, sports events, outings, etc. Nor are educational opportunities neglected: members may attend lectures or participate in seminar and discussion groups, for example. Whatever the scheduled activities, ideally, membership in such an organization will serve to increase the ex-patient's sense of belonging and, concurrently, to decrease his feelings of alienation. However, ex-patient clubs have had only limited success in the United States, in marked contrast to their great popularity and consequent rapid growth in England. Olshansky has analyzed the reasons for the relative ineffectiveness of these rehabilitation resources. For one, members of any given group may be expected to demonstrate marked variations in terms of diagnosis and symptomatology, which would impede the social interaction among group members that is a primary objective of the club. Secondly, ex-patients are reluctant to join such an organization because of the stigma attached to mental illness: the club would serve as a constant reminder of the period in their lives which they are most anxious to forget, i.e., the period of hospitalization. To make matters worse, to date, hospitals and clinics have maintained a relatively permissive attitude toward club membership;

that is, no attempt has been made actively to recruit suitable candidates among their former patients. Finally, Olshansky pointed out that, as a result, those ex-patients who need help most would be least likely to enroll as members. This explanation appears to be valid; however, it cannot account for the fact that the ex-patient club has received a favorable response in England under similar conditions.

The day hospital, night hospital, and week-end hospital. The day hospital, and variations of this institution, which are discussed in further detail elsewhere in this volume, may serve as after-care facilities during the transitional period following hospital discharge, or as an alternative to hospitalization.

Foster home care, the halfway house. Historically, foster home care or family care may be traced back to the care provided for mental patients by the community of Geel, in Belgium. Currently, one type of foster home care program which has been set up in the United States is designed to fulfill the primary needs of the ex-patient by letting him live with a specially selected family for a limited period of time. The principles underlying these programs are similar to those which govern foster care programs in the field of child welfare. Foster care programs have also been modified at times to provide subsidized apartments as temporary housing for psychiatric patients following hospital discharge. As a rule, such installations, which include a variety of after-care facilities, are supervised by social workers.

Halfway houses may follow a variety of patterns.* In general, these are converted multiple dwellings, located in the community, which are supervised by a member of the professional staff of the hospital or mental health agency with which they are frequently affiliated. Ex-patients live together and share facilities in an environment which resembles a boarding house. For the most part, these communities are self-governed, although this is not necessarily so. External activities, that is, recreation and work, may be undertaken on a group basis or arranged to suit the needs of the individual patient.

Rehabilitation for the world of work. Since a major objective of tertiary prevention is to increase the ex-patient's capacity to contribute to the occupational life of the community, this aspect of rehabilitation merits careful consideration. During hospitalization, vocational counseling and vocational rehabilitation services should be provided in every treatment setting. Following discharge, municipal, state, and federal vocational rehabilitation agencies should be utilized to arrange specialized job placement for ex-patients.

The comparatively recent development of sheltered workshops in this country has been noteworthy, although such programs have a long history abroad. In any event, sheltered workshops serve multiple functions. For individuals with a skill, they may

serve as way stations and help them to make the transition from the hospital to regular employment. For others, the sheltered workshop may provide an opportunity to develop new skills and appropriate work habits. And, finally, for that segment of the patient population whose residual defect is of major proportions, the sheltered workshop may provide a permanent refuge.

Rehabilitation centers. Traditionally, rehabilitation centers are concerned with the treatment and rehabilitation of nonhospitalized persons with physical handicaps. To provide this wide spectrum of services, members of various professions, with a variety of skills, are assembled under one roof. Obviously, then, the rehabilitation center serves an important community function. Its services do not extend to the psychiatric patient population as yet. However, in light of the increasing awareness that rehabilitation plays a central role in the implementation of a comprehensive community health program, perhaps it is not unrealistic to suggest that rehabilitation centers will become part of a comprehensive community mental health program within the near future.

Tertiary prevention encompasses a large number of alternative and optional procedures for the after-care and rehabilitation of the former psychiatric patient. The psychiatrist must, therefore, undertake the arduous task of *evaluating* these various resources so that he may help program planners to make appropriate decisions concerning those installations which are needed most and those programs which are most deserving of support. Undoubtedly, it will be necessary to provide a variety of services if the needs of the entire community are to be served adequately. The decision as to which resource should be used for a given patient will then depend upon diagnosis, special considerations, the availability of the resource chosen, and the nature of the community itself.

46.4 TREATMENT OF THE IMPOVERISHED

RICHARD E. BROTMAN, PH.D.

In recent years there has been considerable concern for consolidating, integrating, and coordinating a wide range of educational, social, and medical services to meet more efficiently and thoroughly the needs of the poor. Whether the mental health programs being thus coordinated are appropriate or adequate to deal with these needs remains to be seen. There are in fact strong indications that the usual forms of psychiatric treatment may *not* substantially benefit this group.

If traditional techniques of psychiatric treatment will not do enough fast enough for the poor, what can be done instead? Many helpful new ideas are developing through the cooperation and cross-fertilization of psychiatry and sociology. It is being recognized that many problems in mental illness can result from environmental factors. One new technique, community mental health diagnosis, is essentially concerned with an assessment of the interaction between the individual and his environment and the results of this interaction. Up to now, most attention has been given to particular dysfunctional results and the effects of the physical environment on mental health. The community mental health approach also gives consideration to the texture of the *social* environment—that is, laws, organizational policies of special treatment agencies, and the general, uncodified attitudes and values of society as they circumscribe an individual's position in his community and affect the quality of his life therein.

In poverty as in mental illness, both the *when* and the *where* of the origin of the difficulty are often hard to place. Traditionally, psychiatry has focused on the past, and social reform has focused on the present as a point of departure. Now, however, psychiatry recognizes the influence of present circumstances on present behavior; and the national poverty programs are concerned with childhood cognitive deprivation as a cause of the vicious cycle of indigence. This broadened focus puts us in a better position to deal with the complexities of poverty and mental illness and to see more clearly the characteristics of the affliction and of the afflicted. What are needed are available forms of service suited to the characteristic needs of groups of people, along with a sophisticated diagnostic mechanism capable of bringing together that service and the people it can help.

Evolution of Treatment Programs

Two points must be made at the outset. First, there are not now, nor have there been in the past, any significant mental *health* programs for the poor or for

anybody else. There are, instead, programs concerned with mental *illness* and its prevention or alleviation. The second point is that the poor as a group have been defined into attention only recently. The economically impoverished have existed throughout history, but the poor as a group having singular characteristics (other than lack of money) have not long been the target of services specifically designed to bring them into another condition.

The programs. A mental illness program implies the existence of an agency of some sort. If this were not the case, the effort would not be a *program*. A chronological survey of programed efforts would be quite short, for widespread organization of efforts to deal with the mentally ill by other than individuals—relatives, for instance—is a relatively recent phenomenon.

State hospital programs were the first large scale efforts organized to deal with mental illness in this country. The result is now generally considered to be less than adequate. Dissatisfaction with segregated confinement of the mentally ill has given rise lately to a movement to bring at least the tractable cases back into their own communities. Here they are to receive treatment from professionals, and the treatment is to be supported in some measure by the community.

In the middle 19th century, mental illness was identified as a target for curative medical treatment, and, at the same time, increasing attention was being paid to the living conditions of the lower class. These conditions, particularly in the cities, were unbearable. The main idea was not that such conditions made people crazy, but simply that cities were dirty, crowded, conducive to physical illness, and unfit for children. The foulness of the environment could in some measure be overcome by improvement of the economic position of those living in it. Social reform movements for the betterment of these conditions arose. One aim was certainly to make people happier through environmental repair.

Lately, increased attention has been given to the community specifically as a target in the treatment of mental disorder. In many programs, there is a general movement away from help given by associates or professionals on a one-to-one basis and toward assistance by progressively larger agencies. The movement toward the community mental health center program looks like a return to treatment on the local level, which is in fact where the treatment is *delivered*, but the treatment is bought largely on the federal-state level.

Current treatment programs for the mentally ill poor are focused in cities. Although the implication of the community mental health centers concept is that those in rural areas who need help, such as American Indians and hillbillies, will receive attention, the poor receiving the most attention currently are the urban poor.

The patient. Describing a population as needy has not always been to describe them as unquestionably deserving. In 1848 John Stuart Mill wrote that it required much experience to determine that the poor might be supported "at the cost of other people . . . without fatally relaxing the springs of industry and the restraints of prudence." He went on to say that this support might be given safely only "if the relief, though ample in respect to necessities, was accompanied with conditions which they disliked, consisting of some restraints on their freedom, and the privation of some indulgences."

It is now felt that the poor *deserve* many things they do not have or do not seem to be able to get through their own efforts. Among these things is treatment for mental illness. Ability to pay for this service out of one's own earnings is not to be a limiting factor in the accessibility of such service; neglect is not to be countenanced on the basis of indigence.

A "program" to care for the mentally ill poor does seem to be necessary. The affluent can buy their own services, but the poor may have to be given theirs by society as a whole. The care they usually receive is often quite unrefined, as Coles wrote:

Whereas the wealthy and the well-to-do are more likely to be treated with individual psychotherapy, purchased privately or secured at clinics which largely provide for the middle classes, the poor are usually sent to hospitals and, once there, receive the less humane treatment of electric shock or drugs.

It has been observed that the psychiatric problems of the rich are treated as medical problems, but those of the poor are treated as social problems. The problem, however, is not the relatively simple one of giving the poor services like those the affluent receive. The reason is that the poor do not, in fact, seem to be the affluent without money; that is, poverty is now seen as a syndrome having specific characteristics with other than economic implications. One such characteristic is a trend away from verbalization and toward motor activity. As a consequence of this, it may be speculated that psychoanalysis, a verbal technique, is unlikely to be successful as a treatment for neurotic disorders in poor people.

Another reason treatment programs for the poor need to be different from the traditional ones is that the types of illness from which various groups suffer seem to be related to degree of affluence. Miller and Swanson found that the poor are more likely to develop symptoms such as conversion hysteria and catatonia, which involve malfunctions of the voluntary muscles. Middle class individuals more often exhibit obsessions and depressions, which are characterized by inhibition of voluntary movements.

There is considerable difference of opinion on this point. It is unclear whether poor people get sick differently from other people or simply present a different picture as a group because their illnesses seldom receive effective attention. Then too, there seems to be considerable class bias in the diagnosis of mental ill-

ness. Mental health is practically defined as middle class behavior, which puts the lower class at a disadvantage at the outset; the *reductio ad absurdum* of this is to see poverty itself as a sign of mental illness.

It should be emphasized that the distinction in types of treatment appropriate for the poor is not made solely on the basis of dollar cost or availability of trained treatment personnel. Rather, characteristics of the target population are the crucial factor.

The aims. The initial aim of actions directed at the mentally ill was to relieve the community of a dangerous or troublesome member. No attempt was made to cure the sick. Then this goal of riddance was combined with the humanitarian one of relieving, to some extent, the suffering of the afflicted individual. Then primary emphasis shifted, at least ostensibly, to treatment of the individual, often with the hope that he could be returned to a normal state. Insofar as mental illness is now seen as a form of deviance, emphasis is on eliminating or reducing this deviance.

The techniques. As medicine developed methods for acting on behalf of the mentally ill, the technique of psychoanalysis was developed for the treatment of neurosis. This technique involves one neurotic person in an intense personal relationship with a doctor. It is generally a long process, and its efficacy is incompletely documented.

Subsequent psychotherapeutic methods have been developed and some of them involve a number of ill people in treatment at once. Some of these group methods are less investigatory and more directive; there are indications that they may be more suitable for the lower class.

Organic treatment techniques are highly effective in certain types of mental disorders. The most widely useful of these are the psychoactive drugs. Because they circumvent the special difficulties inherent in the use of middle class verbal techniques, drugs are particularly useful for the treatment of the lower class.

These techniques all concentrate on the individual with symptoms. Lately, techniques have been developed that concentrate on factors outside the individual, and mental illness programs and social action programs have fused. S. M. Miller noted:

Services aimed at individual treatment are not enough. Professionals and their organizations must support and encourage action that will deal with the larger American scene in which poverty is being produced and maintained. The professional [must] pressure for social changes that will make individualized professional service more meaningful and effective.

Cleaning up a neighborhood may be seen as a way to keep the rats out of the living room *and* the bats out of the belfry. Some behavioral correlates of poverty can be eliminated as the conditions of poverty are changed. This may be a treatment measure, but it is also a measure in primary prevention.

New techniques for helping the disturbed individual who is poor have also been developed. Rendering of tangible concrete service, counseling rather than ther-

apy aimed at insight, role playing, and various forms of sociotherapy are among the many techniques used.

The time of treatment. Attention has traditionally been given to the mentally ill at the time at which the illness is most severe; the buildup and letdown phases of the disorder were largely ignored. It is, of course, perfectly reasonable to direct attention to the most obvious point of difficulty. But this kind of attention apparently does little either to prevent a continuous occurrence of dysfunction in society or to rehabilitate the stricken individual. Thus, increasing attention is being given to early detection and precare services and rehabilitative services by after-care and pathway agencies. Essentially, the *before* and *after* phases of treatment are the province of the social agencies, and the *during* phase of severe disability, if it occurs, is the province of the medical services.

The financing. Insurance programs, while not care-giving programs per se, are suited to the poor as an alternative to public handouts, for insurance does plan to give money to those needing it at the time of need. But the lower class, who are most likely to need money in times of emergency—mental illness being one—and are the least likely to have it on hand, are also the least likely to be able to buy insurance privately on a continuing basis.

There is, however, the Federal Social Security program which, under Kerr-Mills, furnishes medical care to the indigent. Public welfare programs generally are also a kind of insurance program, with the premiums being paid by the population at large, including the poor. Welfare programs also offer some kind of psychiatric treatment when indicated. Medicare has made it no longer necessary to be financially poor to receive federal benefits, and these benefits specifically include care for mental illness. All insurance programs that include treatment for mental illness are distinguished by the fact that they make provision in the present for service in the future. They are established with the idea that some people *will* become ill, and they are intended to finance care of some kind for that future illness.

The personnel. In the early days of psychotherapy, the givers of treatment were individual therapists. Where programs existed, they were in privately operated clinics or local hospitals. Then the state mental hospital developed, the programs were operated by state government, and many more indigent individuals came into care. Dissatisfaction with the state hospital system has resulted in the development of the community mental health center idea. Operation of these centers has been dichotomized: large scale financing and direction are moving to a larger body, the federal government; and actual care-giving is moving to a smaller body, the local community.

On the local level, mental health center operators—that is, administrative and line personnel—are obviously going to be needed in great numbers. Medical personnel—that is, psychiatrists—have in the past

been the actual care-givers in mental illness; social pathology has been attended to by professional social workers. But there do not seem to be enough of either of these to go around. Besides, the form of service that has been traditionally rendered may have to be modified to be applicable to or effective with the lower class. New kinds of mental illness care imply new types of treatment personnel with new approaches suited to the needs and characteristics of those in need.

The logical possibilities seem to be these: (1) no professionalization, (2) a congeries of professions, (3) an alignment of professions, (4) a set of new professional specialties, (5) a new profession, and (6) new knowledge for existing professions. The congeries of professions applies to the current poverty movement, where a variety of professionals enter but often seem to function in no specific relation to their professions. An alignment of professions refers to the multidisciplinary team approach, in which existing professional skills are used but are supplemented by a new common orientation. Community mental health programs now function this way, as an alignment of professions, but this movement has not yet produced any new professional specialties. The sixth possibility, that of attempting to widen the range of skills of current professionals, is promising. An example of this approach is the inclusion, in medical school and psychiatric residency curricula, of data about the characteristics of the poor and of techniques for their treatment.

Characteristics of the Poor

Gordon's description of an area in Harlem illustrates the kind of environment in which the urban poor often live:

One in every three families has an income of less than \$3,000 a year, and one in every two adults has had only a grade school education. The proportion of housing units in adequate repair and with private bathrooms ranges from one-half in one tract to less than 10% in another; delinquency rates in 1962 were three times that of the city as a whole; in 40% of the families there is no legal or common-law husband present, and over half of the children of the area live in one-parent households. The buildings are four or five stories with some four apartments to each floor. The mailboxes in the vestibule are frequently without names, and the entrance door to the hall is generally not locked. The halls are dimly lit and made even darker by the dark paint on the walls. The floors may be littered with empty wine bottles, candy wrappers, and just plain dirt. The streets are generally deserted in the early morning hours, but from noon until dark the stoops hold clumps of people—mothers talking, minding children, and waiting for the number of the day, winos and junkies in a world of their own making, and men slouching, expressionless, occasionally bantering with women who pass. One is struck by the number of people on the streets, particularly so many men—going nowhere, doing nothing.

It is not surprising that individuals who have lived in an environment so radically different from the one most middle class people are familiar with should regularly differ from them in patterns of thought and behavior. In fact, a cultural chasm has been described between middle class concepts and those of the lower

class. For example, Riessman has found the following points on the cognitive style of a variety of low income groups to be relevant to the new technology of poverty medicine, particularly as they affect the application of psychiatric service: (1) physical and visual rather than aural; (2) content-centered rather than form-centered; (3) externally oriented rather than introspective; (4) problem-centered rather than abstract-centered; (5) inductive rather than deductive; (6) spatial rather than temporal; (7) slow, careful, patient, persevering (in areas of importance) rather than quick, facile, clever; (8) games and action versus test-oriented; (9) expressive versus instrumental-oriented; (10) one-track thinking and unorthodox learning rather than other-directed flexibility; (11) words used in relation to action rather than word-bound orientation.

It must always be borne in mind that, when one speaks of the poor as a class one is speaking of human beings; their idiosyncrasies and group differences do not override their humanity. Nevertheless, to deal professionally with poor people—that is, to render helpful service to them—one must take account of their significant characteristics, particularly as these seem strange or hard to contend with. If efforts to engage the lower class in a mutual venture of communication and service are to succeed, it is necessary to know the life style well enough to understand their problems and to offer comprehensible assistance.

Attitudes toward time. A frequently mentioned difference between lower class people and the more affluent is in their orientation to time. Stated in rather extreme terms, the difference is this: the affluent are primarily oriented toward the future; the deprived are oriented toward the present and, to a lesser extent, the immediate past. Many middle class people have their time scheduled far in advance. Relatively few engagements have much significance for the moment; instead, many are oriented to the future and are essentially attempts to control the future. Usually, the present is important not for itself but because it offers an opportunity to affect the future. In other words, most activities are not ends in themselves but are means to ends.

Unlike the middle class person, the lower class American is likely to be strongly oriented toward the present or the immediate past. He is not a visionary, with his eyes on the promise of the future. He is a realist who is concerned with the problems and rewards of the immediate present. The present cannot be ignored. Its demands must be coped with; its rewards must be enjoyed now.

There are many illustrations of difficulties caused by this difference in time attitude. The lower class person can feel quite bewildered when asked by a therapist, "What day would you like to come next week?" How can he reply? How can he know how he will feel next week or what he will be doing then? What is there to make one day preferable? Why come next week any-

way, when he is at the clinic now? A particularly serious consequence of the present time orientation arises when preventive measures are refused because the individual feels well at the moment and sees no point in inconveniencing himself now in order to avoid more serious problems in the nebulous future.

Attitudes toward change. Closely related to the attitude toward time are views about change and progress. Our society is highly oriented toward change. Newness has come to be valued for its own sake, and oldness alone—quite apart from any other attribute a person, an object, or an event may have—is enough to make him or it undesirable. Isolated within urban centers and in a precarious equilibrium with their environment, lower class individuals have had little opportunity to experience change. The future, if envisioned at all, is seen as an extension of the present. The lower class person, living in a rapidly changing environment, is handicapped in his efforts to understand change, and he may fear new adjustments. Consequently, middle class persons may be exasperated at what they interpret as lack of initiative, backwardness, or satisfaction with things as they are.

Attitudes toward acceptance and resignation. A trait of many disadvantaged people is their greater readiness to accept and be resigned. Most middle class individuals believe that man must struggle and master the problems that beset him. The disadvantaged person is likely to meet difficulties by adjusting to them rather than by attempting to overcome them. Middle class people feel they must do something about overcoming sickness, and, when death occurs as the result of disease, they say, "We did everything that could be done." When the disadvantaged person is ill, he may seek help, but there is not the strong feeling that he should or must do so. If the disorder comes on gradually and involves no great discomfort in the early stages, the patient and his family may feel no strong obligation to do anything about it. Persons suffering from chronic disease are sometimes completely indifferent to treatment.

The attitude of accepting rather than fighting is sometimes given expression by withdrawal from unpleasant or potentially difficult situations. Lower class persons who need professional services may withdraw if they encounter hostility or if they are being too strongly urged to make a decision or take some course of action they are reluctant to pursue. The withdrawal may take the form of outright rejection, but it is more likely to find expression in polite reticence or a passive refusal to cooperate. The reluctance to come to clinics is a reflection of uncertainty as to what to expect from an employee whose bureaucratic impersonality seems to imply indifference to concrete problems.

Lower class individuals often seek to establish, even in situations that by middle class standards do not warrant them, personal relationships with employers, politicians, and other persons of influence and authority. Consequently, professional people who permit or

encourage a personalistic quality in relationships with lower class patients or clients often find that they are more successful in getting professional help accepted than those who insist on a rather rigid impersonality in their relationships.

Attitudes toward dependence. Among the cherished values of the middle class is a preference for independence and a corollary dislike and distrust of the dependent state. From this point of view, independence can hardly be overdone; dependence, even of a relatively slight degree, is regarded as undesirable if not downright pathological. They like neither to be dependent nor to have others dependent on them, and an implicit obligation of one who receives help is that he will at the earliest possible moment take whatever action may be necessary to make himself independent again.

Among welfare workers and other professional people, there is considerable expression of misgiving lest their efforts somehow damage the characters of those to whom they give services by making them more dependent. It is widely held that people should be helped to help themselves, and a good proportion of institutional services are deliberately designed to transfer people as rapidly as possible from a dependent to an independent state. But among deprived people, independence is not given nearly so high a value. The unit of independence tends to be the extended family or the local neighborhood rather than the individual.

Dependence, then, has one meaning for the lower class person and quite a different meaning and significance for the more affluent person. Those who accept help from another individual or an agency are, in the middle class ethos, supposed to do so reluctantly and to feel obligated to exert every effort to become independent at the earliest possible time. The deprived individual who accepts professional or institutional assistance is expected to feel the same way. But to the extent that his attitudes and actions derive from a different locus, he is likely to view the giving and accepting of assistance as the normal and proper functioning of an institutional relationship in which both parties to the relationship are simply doing what comes naturally. Traditionally, people helped or were helped as the need arose, passing in and out of dependency relationships with no thought that a dependent status might be wrong or dangerous or undesirable. Thus, professional people and agencies are expected to give help because this is their function. The individual needs help, and so he accepts it for as long as it is available and usable. There is nothing in the relationship to get excited about, and certainly no cause to terminate it while need—subjectively defined—exists.

In these attitudinal differences lie many of the bases for misunderstanding between the lower class individual and the treatment agent. As long as these differences exist, some mediation mechanism between the population in need and the care-giving system is called for.

Policies toward the Poor

The present policy toward the poor has developed through a series of approaches that have left lasting effects even as they have been largely superseded. According to the schema developed by Silverman, the major movement is from a model based on humanitarianism to a model based on national effort. The former is individualistic, and the latter is societal in outlook. Within the two major themes there is a movement over a pair of minor themes. The humanitarian model moves from a charity theme to a nondiscrimination theme. The national effort model moves from a new technology theme to a juridical theme.

Charity. Charity is an obligation on those who have means to care for those who are in want. In Judeo-Christian cultures among others, it is important to understand ethical demand. The one who gives gains prestige, and the one who receives may have his sense of social solidarity reinforced. Ideally, then, a main societal function of charity is social integration.

What are the shortcomings of the charity model? On the one side, to receive charity is more likely to be alienating than integrating because it conflicts with an ideal of independence and self-sufficiency. On the other side, there is a tendency for the giver to discriminate between the deserving and the undeserving poor. To be deserving generally means to satisfy the prejudices of the giver. Such discrimination perverts charity, which derives from a concept of Divine love, into a means of social regulation.

Nondiscrimination. It might be difficult to explain to the Lady Bountiful of the 19th century just what the public assistance worker of the 20th century is up to. Basically, he is administering a set of insurance schemes. Anyone may apply for benefits as a matter of right; and he will receive them as a matter of right if he has satisfied the impersonal and objective criteria of eligibility. One attractive feature of this scheme is that it covers everyone equally against the risk of indigency, regardless of his body weight or skin color or morals or social class.

Medical care also falls under the nondiscrimination model. Public and private sources along with the medical professional either cover or forgive any of the costs of medical care that the individual cannot meet. He is entitled to the best of care, no matter who he is or what he can pay.

The nondiscrimination model corrects many of the defects of the charity model in a most tactful way. But tactfulness is also its defect. It resolves to treat every class of man in the same way, and so officially it cannot ever distinguish one class from another. Therefore, it cannot ever notice that one class is not doing as well as another. And it cannot notice that procedures that work for one class may not work for another.

The various social classes, whose very existence is an embarrassment to the middle class, are in many ways separate countries whose ways are foreign to

each other. Subcultural differences can make a big difference as factors in disorders of various kinds and in the bringing of these disorders to the attention of agencies. Most care-givers are most at home in the middle class. The cultural characteristics of other classes, if they are to be taken into account, become objects of technical knowledge.

The new technology. The new technology model is used by professionals when they move into unfamiliar ground. It is a searching for knowledge, materials, and instrumentalities that will confer an ability to predict and control. Just as the space program has brought the new technology of space medicine to deal with effects of radiation belts and conditions of weightlessness, so the poverty program has brought the new technology of poverty medicine to deal with its raft of exotic concepts.

The new technology model, in and of itself, has no controlling morality. It was applied to problems of discovering and administering polio vaccine. And it was applied by the Third Reich to the problem of carrying out a policy of genocide. The memory of the latter example makes people uneasy where the object of the search for technical knowledge happens to be a group of people. They feel the need for principles that will set limits.

The juridical model. The juridical model uses democratic legal machinery to do social engineering, that is, to bring about changes in social institutions. Many laws, such as those on kidnapping and tax evasion, depend for their fulfillment on the fact that they are in harmony with the institutional status quo. But laws making alcohol illegal or school integration mandatory fall under the conception of the juridical model because they require changes in the design for living of many citizens.

The juridical model has certain hallmarks that may help to make it more recognizable and more comprehensible. There is at least some sociological sophistication in the use of this model, such as an awareness of the interdependence of institutional spheres, if social engineering is seriously attempted. And if there is indeed democratic use of the law, there is a concern for principles of justice and due process.

The right to counsel. Competent professional care for ills in society is nominally a common right. But the quality of such care varies directly with social class. Reliable access to care of high quality is a class privilege, and the goal must be to change it into a common right. But how can such a change be brought about? It will require a larger system of care, but of what kind? The same kind of system will probably give the same kind of results as before. A treatment program is in itself a social system with functions to perform for its own members. The poor would remain customers of the program but not members. On the other hand, a brand new system will probably give worse results than before simply as a result of sudden discontinuity.

Something that will work within the existing system is needed to transform it into something better.

One suggestion that may aid in meeting this need is drawn from the juridical model. It is both a due process and a social engineering conception. A perpetual role of government is to issue laws with punitive provisions, thereby putting citizens in jeopardy of the law. The legal system has developed and strengthened a conception of the right to counsel for the citizen in the face of jeopardy that is backed by the power of government. But what of the laws that create programs for service to populations at risk? The same elements of governmental power and citizen's jeopardy are involved; only the direction of action is reversed so that risk is to be removed rather than imposed. In addition, the dimensions of the present effort begin to suggest the *enforcement* of service, rather than its mere extension. The citizen is again entitled to due process. He should not be expected to face the Leviathan alone when his life chances are at issue. To make the encounter more nearly equal, programs of aid should institute the right to counsel.

The type of counsel needed is as much an agent or a broker as he is a lawyer. His duty is to help his client overcome ignorance, error, and adversity in facing the care system. He is an officer of the care system, but one who is charged with standing against it on behalf of his client. He is an adversary to his brother officers in the system whose interests are tied to the success of the program. It is precisely the issue of conflict of interests that calls for the separating out of the counsel's role in the care system. On the other hand, such a role cannot be divorced from the rest of the system because its enactment calls for an intimate knowledge of the actual operations of the care system in a particular place at a particular time.

It is doubtful that any one mechanism will do the entire job. But the principle should be given consideration by those involved in the creation and operation of treatment programs. For the client in any transaction to derive maximum benefit from the transaction, he must be able to use the product and be able to negotiate the system through which he obtains it. On the seller's side, he must understand what the client wants, have a product the client can really use, and have an efficient method for getting it to him.

46.5 MENTAL HEALTH CONSULTATION

MILTON GREENBLATT, M.D.

Growing awareness of community mental health needs and the vast expansion of the psychiatric frontier have served to point up the current shortage of mental health manpower and the need to develop methods that can extend the range and effectiveness of professionals in short supply. Mental health consultation emerges as one such method particularly worthy of attention in this era of community psychiatry, with its emphasis on prevention, environmental and cultural influences, early case detection, early intervention and crisis alleviation, and the high premium placed on brief and effective contacts.

The Joint Commission on Mental Illness and Health, aware of the manpower shortage, recommended training large numbers of mental health counselors, who could work under the direction of mental health consultants and give services to neglected areas. The great unmet needs for such services are equalled by the paucity of training for consultants. It is fair to predict that consultation skills will be more in demand in the future and that some training and practice in consultations may become part of the requirements of many, if not all, young psychiatrists of the future and probably many psychologists and allied professionals.

Definition

What is mental health consultation? It is usually defined as an interaction between a consultant and a consultee on behalf of a client. The consultant is a person with specialized knowledge in the mental health field; his consultee requests help in increasing his skills in handling a disturbance, crisis, or troublesome situation or in raising the mental health of a person or group for whom he is responsible. The client may be an individual, a group, an agency, or an institution.

Thus, the concept of mental health consultation is broad and susceptible to multiple interpretations. Within its boundaries it would be possible to include the familiar model of aid given to social workers in community agencies by consultant psychiatrists; the supervision of psychiatric residents in training in their individual, group, or milieu problems by senior faculty; legal counsel given by lawyers to psychiatric administrators; editorial suggestions given to psychiatric journal editors in regard to articles submitted for publication; the supervision of mental health researchers; and the consultative assistance by a broad range of professionals and laymen given to organizers of mental health programs.

Procedure

The procedure of mental health consultation begins with a *request* from a consultee sanctioned by his agency and his authority figures. The consultant and the consultee meet together over a specific problem with the expectation that the problem can be alleviated or resolved within a short time. Through study, education, or specific actions, the knowledge of both is used to arrive at a reasonable solution.

To be maximally effective, the interactions must avoid certain pitfalls. The consultant must maintain objectivity. He must strive for good will within the organization he serves by maintaining a continuing satisfactory level of sanction from the key figures in the hierarchy. He needs the patience to permit the relationship to mature to a point of real effectiveness. He must facilitate—not dominate or make dependent. He cannot be judgmental, delve too deeply into the motivational aspects of the consultee, or practice psychotherapy.

Caplan, whose experience is considerable, advocates strongly a work-oriented and not a psychotherapy-oriented approach. He points out that the basic contract for psychotherapy is not present and that there is no framework within which to deal properly with psychological resistances. Further, psychotherapeutic maneuvers are likely to threaten the consultee and alienate the group he represents.

If the consultation proceeds properly, the consultee's anxieties will be considerably allayed and his effectiveness thereby increased. Review of the situation with a trained objective person yields considerable clarification in diagnosis and opens up new attitudes, methods of procedure, and avenues of communication. Without the consultant taking over, a relatively small amount of his time—judiciously employed within the consultation framework—can be of enormous help to a client or organization.

An interesting case in point was reported by Wodinsky, who is concerned with the establishment of psychiatric liaison with medical and surgical services in general hospitals. Serving primarily in a consultant role, his task was to help nurses establish a better therapeutic milieu on a leukemia service. This involved

helping the nurses to understand their relationship with patients, doctors, and each other; to reduce their anxieties; and to tolerate the frustrations inherent in a difficult environment. The method employed individual and group discussions with nurses. Feelings of hopelessness, helplessness, guilt, and fear of death could be expressed, shared, and understood. These feelings separated the ward nurse from the patient and induced intolerable feelings of abandonment in the patient. Relationships to families who cajoled, criticized, chided, or obstructed treatment also received special attention. The doctors were often seen by the nurses as either omnipotent beings or cruel experimentalists. Wodinsky showed clearly how a psychiatrically trained consultant, without probing the deeper roots of conflict, may be of inestimable value in a sensitive work situation where support and understanding are primarily employed.

Research and Educational Potential

The consultation method can be applied over a wide range of mental health activities. The consultant does not necessarily have to know all about the field of endeavor in which he is consulting or become an expert in the area in which his consultee is practicing. Instead, he can provide great assistance with his general knowledge of psychiatry, psychology, and mental health and his specific expertness as a consultant trained in objective analysis, development of relationships with consultees, and sensitivity to how the latter's anxieties diminish his effectiveness. Since every consultation is in itself a learning experience for both parties, the consultant can greatly extend his awareness of problems and activities in the mental health field and open up channels of new information regarding community mental health practices, cultural values and influences, group interrelationships, and social forces leading to disease, crisis, or health. The consultation, therefore, may be useful in many research and educational contexts in addition to its value for service.

Training for Mental Health Consultation

Greater emphasis on mental health consultation training may be expected in the future. Exactly how this will be organized is open to trial, error, and experimentation. Only a handful of training programs in psychiatry make formal attempts to teach consultation.

Recognizing that no final answers can be given at present, one might suggest that, in order to be prepared for consultation work, one should have considerable experience in psychiatric diagnosis and treatment together with intensive grounding in individual and group dynamics. In addition, experience with other groups in the community whose values and attitudes are different from the trainee's would be worthwhile. An academic background in community and social psychiatry with some basics in the social sciences is recommended. Specific training in community psychi-

atric practice—as in a home treatment service where mobilization and coordination of practitioner, social agency, schools, clergy, and police are required—is almost a necessity. Finally, specific consultation activity in several settings under supervision and the opportunity to study and criticize procedures and results and to formulate theoretical views in a seminar-type conference over a considerable period of time are most important.

46.6 ROLE OF COMMUNITY MENTAL HEALTH WORKER

MILTON GREENBLATT, M.D.

The present trend in psychiatry is to treat illness *where* it manifests itself and *when* the patient needs help, through mobilization of all relevant community resources in the immediate environment. Hospitals and mental health centers are assuming responsibility for identifiable sections of the community and are attempting to know all about these areas—their history and development, inhabitants, values, cultural modes, leadership, civic organizations, police force, schools, religious institutions, social welfare resources, and politics—with a view to assessing factors and influences leading to health and disease and ways to bring these forces under control or modification.

Mental health professionals must identify and relate themselves to all those who could be of aid to sick individuals before, during, or after hospitalization. They should take the initiative in educating or training these mental health workers, who have diverse capabilities, orientations, and potentialities.

Estimates of prevalence of mental illness in the community are surprising and alarming. The Midtown study suggests that a majority of Americans in

New York City either are consulting professionals for emotional distress or have illness of a degree that warrants such consultation. Data from Los Angeles indicate that about 3 to 4 per cent of adults have at some time in their lives made a suicidal attempt. *Action for Mental Health* reveals that one out of five people surveyed felt at some time that he was going to have a nervous breakdown. About one out of seven patients from a representative population sought help at some time, 42 per cent for problems relating to marriage, 18 per cent regarding matters of personal adjustment, and 12 per cent regarding their children.

To whom did these troubled people turn? Some 42 per cent went to the clergy, 29 per cent to general practitioners, 18 per cent to psychiatrists or psychologists, and 10 per cent to social agencies and marriage clinics. Of these, 58 per cent said unequivocally that they were helped; 14 per cent said they were helped, but they expressed some reservations; and 20 per cent said they received no help.

An additional 1 in 10 persons recognized that he had problems that might have benefited from professional help, although he did not actually seek it. They turned, instead, to spouses, family, or friends, or they prayed or did nothing.

Of great significance from the standpoint of national planning is the fact that the better educated, younger, urban citizens are the ones who are more able to obtain help in times of need. In rural situations either the facilities are grossly lacking or the citizens are far less motivated. In their Connecticut study, Hollingshead and Redlich demonstrated that mental illness predominates in the lower classes, for whom the chief pathways to therapy are via hospitalization in state institutions. It is clear to those responsible for hospital and clinical services that new methods must be devised in many parts of the country to reach the poor, the underprivileged, the uneducated, the foreign-born, and the Negro. Many Negroes are reluctant to go to clinics dominated by white professionals and white philosophy.

With so much need, such a great poverty of psychiatric manpower, and the tendency for people in trouble to turn first to untrained family and friends and only secondly to clergy and nonpsychiatric physicians or social agencies, it is obvious that a great task lies ahead in bringing aid, whenever and wherever needed, to people with emotional crises. Meanwhile, many are cast in the role of mental health confidant who do not define themselves thus; nor are they prepared, trained, or properly guided for such critical service to their associates.

The Clergy

Troubled Americans often turn to the clergy. Fortunately, hundreds of pastoral counseling programs are being offered in seminaries, and some thousands of clergymen have taken formal courses in mental hygiene. Since the clergy outnumber psychiatrists 35 to 1

and are the immediate resource for so many patients, whatever is invested in their education seems to promise considerable mental health dividends.

Weiner et al., in their study of the clergy in the Dorchester community of Boston, interviewed parish priests, Protestant ministers, and rabbis representing 73 per cent of the total available pastors and curates in the area. Of the entire sample, only two said they saw no mental patients during the previous year; the case load for those who did see mental patients ranged from 1 patient to more than 300 a year. Of the total of 2,411 patients or potential patients seen by this group, 327 had had previous psychiatric treatment, and 68 were being seen concurrently by a formal therapist, not necessarily a psychiatrist.

The studies of Weiner et al. reveal in the clergy an inverse relationship between training in psychology and age, the younger clergymen having received more formal instruction in psychology. Those with more instruction knew that the private psychiatrist and sectarian counseling services were available as consultant resources. Those with little or no training were unaware of any consultant resources. Some 20 per cent of the clergy were not aware that consultant resources of any type existed. All the clergy were less sure what to do with hospitalizable patients than with nonhospitalizable patients, and clergy with the least formal course work in psychology demonstrated the poorest use of available dispositional resources outside of the hospital. Those with less training tended to use the police rather than professional psychiatric resources.

The study concludes that the clergy who play an active role with psychiatric cases do so in relative isolation from psychiatric resources and that psychiatric institutions could fill this gap by providing assistance in case finding, rehabilitation, and care-taking and in defining the clergy's ancillary role in the treatment of patients who resist psychiatric referral. The clergyman obviously occupies a sensitive position in the community and is a key resource in every aspect of community programs. It is now psychiatry's responsibility to recognize, accept, and support what the clergy is able to offer.

Much could be done to bring the clergy properly into the therapeutic orbit as collaborators with psychiatric professionals. Toward this end, for example, seminars for theologians of various denominations have been arranged in the Dorchester area of Boston by Drs. Becker, Drouin, and Weiner—with considerable success. These seminars discuss case examples from the experience of the clergymen against the background of the psychiatrist's knowledge. Hospital training programs for theology students and for graduate clergy have been in existence for some time in mental hospitals in collaboration with schools of theology. Here case study, group seminars, ward observation, and social therapy participation are incorporated into a larger program.

There are hundreds of centers for the training of

pastoral counselors. Some are connected with their church of origin, and some are not related to a church group. Many of these give diplomas or certificates for work with mentally ill cases, and some have requested aid from psychiatrists, either in planning curriculum or in actually conducting training courses or seminars. Several national organizations, such as the Institute of Pastoral Care, help bring the clergy and psychiatrists together.

General Practitioners

Since the majority of patients going to physicians for medical ills either have an associated emotional disorder or primary mental disease, general practitioners are deeply involved in the care and treatment of the mentally ill. In addition, the second most sought resource for those with a primary emotional disorder is the general practitioner. Although psychiatrists have long been somewhat estranged from their medical colleagues, it is now recognized that collaboration between psychiatry and medical practice is a necessity for optimal service to the sick.

General practitioners recently graduated from medical schools and hospital internships are better oriented toward psychiatric thinking than those graduated years ago. Unfortunately, practitioners are so busy that they are often not inclined to give psychiatric patients the attention they require. It is not only costly in time and money, but their training and experience do not equip them to understand and tolerate bizarre symptoms.

Brown, in a study comparing general practitioners with psychiatrists, stated that with few exceptions general practitioners find symptoms such as aggressiveness, hallucinations, delusions, and suicidal gestures grounds for immediate referral to a mental hospital. Psychiatrists, by contrast, are much more comfortable with these manifestations and are better able to handle their own anxieties in coming to an appropriate decision about hospitalization.

A study by Weiner from Boston State Hospital indicates that general practitioners are especially sensitive to the feelings of the community and family in making a referral to a psychiatric physician or to a state hospital. The stigma and negative attitude of the community toward psychiatry and the mental hospital are often shared by the physician. Further, the relationship between the general practitioner and the psychiatric profession is far from ideal. For example, mental hospitals often do not take the trouble to inform the practitioner of the clinical course of the patient he has referred for admission. Yet, because he has a well established place in many families, he is a potentially critical agent in early case detection, treatment, and rehabilitation.

How can the general practitioner and psychiatrist be brought closer together in the interest of the patient? On the medical school level, the teaching of psychiatry is assuming an increasingly important role. In the future, it is hoped that medical schools will so

train all physicians that they will be qualified to manage most of the psychological disturbances they encounter in practice, referring only the most disabling ones to psychiatrists. In this way, the general practitioner will be a true community mental health worker. As to training the present generation of general practitioners in psychiatry, the National Institute of Mental Health has inaugurated a successful program to facilitate postgraduate instruction in psychiatry. From such programs, some general practitioners have returned to their work considerably enlightened about the handling of patients with emotional disorders. Many courses and seminars have been held for practitioners, but they usually involve only about 10 per cent of the physicians in a given area. In several states, attempts have been made to open up wards in hospitals for patients referred by practitioners where the latter can relate to the psychiatric team. Hospitals are trying to bridge the gap by closer work on individual patients, refresher courses, and teaching institutes. Progress has been slow, but definite gains are being made.

Teachers and Guidance Counselors

The school system provides an excellent entree into the lives of students and, through them, into their families. School children can be observed from an early age, and significant behavioral problems can be followed from childhood through adolescence. Teachers can function in many capacities when properly alerted to mental health problems. They can detect early deviations, request consultations, provide information of diagnostic or treatment significance, participate in treatment planning, and execute a rehabilitation program. Their relationship with the family provides a fulcrum by which parent participation and education can be developed, and the Parent-Teachers Associations are an excellent forum for mental health education.

As sophistication grows and school budgets increase, special guidance teachers have been employed to help school children with their careers and to handle adjustment problems as they arise. The system has been elaborately implemented in some colleges, which now employ teams of psychiatric specialists who may see approximately 10 per cent of the student body during their college career. There is every indication that such psychiatric consultation and guidance are of valuable assistance to the young person to tide him over a crisis; coming as it does in a critical period of his growth and development, it may have a lasting effect on his mental life and alter forever his attitude toward mental illness and health.

In college programs for teachers, the role of a psychiatric consultant has been explored in curriculum development, analysis of training techniques, instruction concerning normal and abnormal growth and development, and diagnostic assistance directly to students and educators.

Social Agencies

In the modern metropolitan city a great variety of agencies deal with every type of human problem, including welfare needs, legal counsel, housing, home-making, family crisis, and child welfare. Some of these agencies are now being amalgamated into multiservice institutes under the antipoverty program. These agencies have tended to develop a selective clientele or to specialize in relation to available manpower or manifest interest of staff. In some cases, efforts are duplicated, or difficult clients are shunted from one place to another in the hope of finding a person who really takes interest and responsibility. Many students of social organization find these agencies poorly coordinated to take care of the whole person. Proper integration of services constitutes a great challenge.

Within these agencies are a legion of potential community mental health workers. Many have long sought and received consultative and educational help from psychiatric professionals. Some mental hospitals have taken the lead in providing educational seminars.

Public Health Nurses

One link between mental health and public health is the public health nurse. Within her district, she has access to many homes and knows patients and families well. She is in a position to note mental symptoms and to undertake the rudiments of mental health care, provided proper guidance is given. In after-care or pre-care programs of some hospitals, psychiatric personnel and public health personnel meet to share information on the patient and to provide continuity of responsibility. Education of the public health nurse through psychiatric consultation, seminars, special courses, and collaborative work on individual cases and families will go far toward increasing their value in mental health programs.

Families of Patients

Since mental illness is born and bred within families and since family members are participants in the sick relationships that have led to the breakdown, it is imperative to reach families for prevention, early case detection, and cure. Individuals afflicted by painful emotional problems very often turn first to family members as an initial line of defense; when this barrier is broken, the clergy and the medical profession are then approached.

How can families be reached and helped to become allies in mental health work? A great potential exists in the families of the mentally ill who receive treatment. In Massachusetts, for example, it is estimated that 1 out of 10 citizens will be hospitalized at some time during his life. Within a relatively short period, therefore, it should be possible to reach a significant portion of the families in the Commonwealth. If proper attention were paid to them—if they were educated, oriented, and brought into the therapeutic orbit—a considerable task would be accomplished.

Families can be reached by group meetings with

those families who have patients hospitalized or attending out-patient departments or after-care, day hospital, or night hospital programs. Sessions of patients and families together have proved to be a powerful vehicle toward emotional development of family members. In those clinics where individual psychotherapy is the idiom, it is almost always fruitful to refer selected family members to the psychiatric team for attention. As a method of crystallizing the family's positive relationship to mental health, it is often helpful to organize some type of voluntary role in support of the clinic that serves them.

Volunteers

A great mass of citizens may become enlightened mental health workers by volunteering in mental health services. In recent years the movement has grown very large indeed. It includes both students and adults from all walks of life. Participation in mental health work under guidance is beginning to be recognized as a force for psychological growth and sophistication. It is also a powerful recruiting instrument for mental health careers.

An example of how mental health workers are prepared by volunteer work is contained in the history of the student volunteer movement in Boston. Originated by Harvard and Radcliffe students, it later spread to many institutions for higher learning in the country. The students have given generously to mental patients in back wards of hospitals, acting as social work case aides, ward aides, occupational therapy aides, research and laboratory assistants. Students have also established a cooperative halfway house, with patients and students living together in a rehabilitative enterprise. Community volunteering in relation to patients in after-care has also been developed.

Adult programs include groups of every description. The movement is growing rapidly as citizens find both challenge and enjoyment in helping the rehabilitation of patients. At the same time, hospital and clinic personnel are learning to trust the volunteers and are using their considerable talents in the common cause.

Chapter 47

Geriatric Psychiatry

47.1 • • •

ALVIN I. GOLDFARB, M.D.

For want of a better term, special psychiatric attention to the aged may be called "geropsychiatry." Because of the interweaving of physical, psychological, social, and economic factors in the etiology, aggravation, or exacerbation of disease in aged people, they and their families have special needs. These needs affect the psychiatrist's allocation of time and his institutional affiliations and favor the development of special skills and treatment techniques.

In the past, there was a tendency to overestimate the importance of brain dysfunction and brain damage in the etiology of mental disorders of old people. This often led to pessimism about the outcome and the value of treatment, and at times it led to relative neglect. However, depressive reactions and emotionally or psychologically determined disorders of thinking and perception are very common in old age and are found in association with organic mental syndrome as well as in relatively pure form. Recently, there has been increased attention to the contribution made by genetic factors, life experience, and immediate circumstances to maladjustment in the aged, whether or not brain syndrome is present.

Endogenous, psychogenic, or functional mental disorders of youth may persist into, recur in, or first emerge as significant in old age. Among the patients with disorders that begin earlier in life are the large numbers of persons who have aged in psychiatric hospitals. Persons 65 years and over account for about 30 per cent of the mental hospital population; however, less than half of them were first admitted in old age.

Persons who have aged in the hospital or who have long term and recurrent mental disorders that begin before the age of 65 fall more in the province of general psychiatry and hospital psychiatry than of geropsychiatry. They are mainly chronic schizophrenics, most of whom require continued care within a protective setting. If they are meek and mild or well

adjusted to institutional life, they are often considered to be candidates for transfer to nonhospital institutions. However, usually this transfer is not a return to the community but merely a shift from one institution to another that is not necessarily better or more helpful to the patient. When more attention is paid to these patients, their seeming deterioration is eliminated or decreased, and their sociability and productive capacity are increased. Because they have lost their places in the community, the most humane care may be the provision of a variegated community within a hospital setting.

This chapter is more concerned with those disorders that develop in old age in association with illness, physical or mental impairment, and the changes and stresses of chronological and functional aging. Persons whose mental disturbances develop or emerge as significant in old age are the true geropsychiatric problems. Their mental disorders can be subdivided into two major groups: (1) disorders of affect or content in the absence of evidence of brain damage and (2) disorders related to brain damage as reflected in brain syndrome.

In the first group are many persons who are relatively ill equipped to cope with the problems that accumulate with the years and others who, although psychologically adequate, meet with unusually stressful situations. In some, life-long patterns of behavior, previously marginally adequate for social adjustment, emerge in old age as full blown mental disorders. Still others have suffered with illnesses that were masked because of special personal attributes or circumstances. The most common psychiatric reaction in the chronologically old is depression, often with paranoid trends. Many aged individuals with these disorders of affect or thought content respond as well to psychiatric care as do younger persons with similar disorders. The need for immediate and short term psychiatric care of chronologically old persons with depressive reactions requires a great expansion of out-patient clinics, private care, and in-patient psychiatric services.

The second group of geriatric mental problems can be subdivided into (1) persons with acute brain syn-

drome: transient severe mental impairment, usually related to illness or intoxication; (2) persons with relatively uncomplicated but irreversible mental impairment: chronic brain syndrome; and (3) persons with disorders in which a mild or moderate chronic brain syndrome is joined by complicating disturbances of affect or content.

Patients with acute brain syndrome are in need of intensive medical care. Persons with severe brain damage are likely to die within a few years; they often require continuous institutional care. Individuals with disorders of affect or content associated with mild to moderate brain syndrome usually improve with psychiatric treatment, but their complete social recovery cannot be expected; they too usually need continued supervision and protection under medical auspices.

Invalidism or disability in the aged can often be averted or deferred if acute, reversible states of mental impairment are promptly recognized and treated. Acute brain syndrome can occur either in the absence of irreversible brain damage or episodically in persons with chronic brain syndrome. Common conditions provocative of acute brain syndrome are infections, pain, fractures, malnutrition, heart failure, coronary thrombosis, drug intoxication, malignancy, and emotional overreaction. The outlook for improvement in mental functioning is good if the patient survives the underlying disorder. Prompt general medical treatment of the underlying conditions and insurance of adequate cerebral, circulatory, and metabolic support, including protection from situations provocative of fear and anger, are indicated to prevent irreversible brain damage.

Persons with moderate or severe chronic brain syndrome generally require a protective, psychiatrically oriented environment such as can be provided in a good residentially comfortable psychiatric hospital. Many old age homes and nursing homes have, in effect, become such units. On the other hand, psychiatric hospitals, which should fulfill this function, often fall short of doing so. State-financed mental hospitals and locally supported institutions, eager to hold their expenses low or to select recoverable cases, tend to define their roles so that the care of the aged mentally disordered is made the responsibility of other institutions. Some planners have recommended general hospital care or the transfer of geriatric patients to old age and nursing homes as an alternative to the use of state hospitals. Actually, there are few geriatric patients in state mental hospitals who have no medical or psychiatric need and who do not belong there, and it is more the exception than the rule for aged persons to be mistakenly referred and admitted. It is true that many aged patients can be cared for in nonhospital institutions which provide comprehensive medical care and admit the patients promptly at times of crises or prophylactically. However, good care for an aged patient is inescapably expensive wherever it

is provided because the needs of the patient remain the same.

Because of the interwoven medical, psychological, economic, and social problems of the mentally disordered aged, they need comprehensive medical care in every setting—whether in their own home, an old age home, a nursing home, a general or a psychiatric hospital—and in this care the psychiatrist should play an important role. In general, so far as in-patient care and treatment of the aged is concerned, where medical care is good, psychiatric care should be improved; where psychiatric care is good, medical care should be improved; where both are good, social services should be improved. Not only are individual psychiatric and group treatment methods likely to help older persons, but frequent psychiatric conferences for staff members and psychiatrically led seminars have a morale-sustaining, stimulating, and beneficial effect for all concerned.

Definition

It is customary to regard old age as beginning with the 65th year. However, aging is best defined in functional terms as an inevitable, progressive process of impairment in the capacity to adapt, adjust, and survive. The aged state, then, is a condition in which decline of functional capacity—physical, mental, or both—has become manifest, measurable, and adaptively significant. Sensory and motor impairment is prevalent in persons who have reached 65, but the truly aged are generally older persons in whom there has been functional decline that significantly affects total functioning. Because of their physical or mental impairment, they usually require special social or economic protection, supervision, and care. Many persons are not able to fulfill even the expectations of a society that tolerates a considerable degree of functional decline and ascribes a special role to the chronologically old. The aged, therefore, may arbitrarily be defined as persons who are 65 years of age or over or who, although younger, have suffered physical, mental, or socioeconomic reverses characteristic of the older group.

Epidemiology

The increased need for geropsychiatry is partly a result of the absolute and relative increase in the number of aged persons in our society. In 1900 the chronologically aged made up about 3 per cent of the total population in the United States. Today, they make up about 10 per cent of the population, nearly 20 million persons. The number of aged persons has tripled, and the medical and psychiatric problems they present have multiplied even more. The admissions rate to mental hospitals, for example, is higher for persons 65 years and over than for any other age group, and their rate of release alive to the community is the lowest. Less than 10 per cent of persons first admitted to state psychiatric hospitals in old age have

a functional, as opposed to an organic, mental syndrome; this small group contributes a disproportionately high percentage of releases alive.

Unquestionably, current estimates of the incidence and prevalence of psychiatric disorders, especially the functional type, are too low.

Admissions to public mental hospitals do not give a true picture of the probable incidence of functional mental syndromes in old age. Functional psychoses afflict a higher proportion of the aged persons admitted to private psychiatric hospitals and the psychiatric units of general hospitals. Nor do hospital statistics reveal the large number of aged persons with affective disorders who remain in the community under the care of private physicians, in private hospitals under general medical care, or receiving no care, since mental illness in the aged may be tolerated as a normal emotional and intellectual effect of aging or dealt with as a legal, administrative problem.

Recent psychiatric examinations of representative samples in a New York City housing project found that 25 per cent of the aged had functional disorders. The Newcastle-on-Tyne survey of Kay, Beamish, and Roth revealed that about 30 per cent of persons 65 years and over have some form of functional mental disorder, two thirds of them mild or chronic neuroses or character disorders.

The disproportionate increase in admission to psychiatric hospitals and other institutions and the prevalence of depressive syndromes in the aged population at large have been deplored as evidence of loosened familial ties. Both of these problems are attributed to a change in attitudes of families and a developing cultural tendency to reject the aged. However, worship of youth and rejection of the old do not

FIGURE 2. Average remaining years of life for white males in 1900-1902 and 1959. (From *Vital Statistics for the U.S.*, vol. 1. United States Department of Health, Education, and Welfare, Washington, 1959.)

seem to be the true causes of these problems. Smaller houses and apartments, the fact that women now work outside the home, the increased mobility of families, improved diagnosis and utilization of institutions, an increase in the number of facilities for care, and the increased economic independence of aged persons who receive social security benefits or welfare and care have all played a part in separating old persons from families. Also, there has probably been a true increase in the number of maladjusted aged for other reasons.

In societies where socioeconomic conditions are poor, where sanitation, housing, and public health facilities are absent or rudimentary, and where medical care is inadequate, the proportion of chronologically aged persons is about 3 per cent. The proportion of aged nonwhite persons in this country has, until recently, been similarly low, and these survivors appeared to be exceptionally hardy (see Figure 1). An important reason for the increased need for psychiatric and medical services by the aged may be the relatively recent preservation of many average persons into old age and not only, as in the past, of the stalwarts (see Figure 2).

Culture and Care of the Aged

Attitudes and practices with respect to the aged, the ill, and the weak appear to be determined largely by a society's survival needs and cultural traditions. In root- and berry-gathering primitive groups, the aged receive no special protection; they survived only as long as they were able to provide for themselves or to dip into the small communal stockpile. In nomadic hunting societies, where survival depended on rapid, efficient movement of small groups from one seasonal

FIGURE 1. Average remaining years of life, nonwhite male and female, and total white population. (From *Vital Statistics for the U.S.*, vol. 1. United States Department of Health, Education, and Welfare, Washington, 1959.)

hunting ground to another, seemingly drastic methods of relieving the group's burden of aged persons were adopted. In one Eskimo culture, an aged female whose contribution to the group had become minimal and who could not keep up with the dog sleds would be left in a temporary structure with a supply of food and fuel, to "recover" while the group continued its journey, presumably to return later. After she and her family sorrowfully acted out this play at temporary separation, she lay down to die, and they mourned her at a distance, as was ritually prescribed. In such societies, few males survived to be social burdens. When a man did, he might, at his own request, be mercifully put to death by a son. In such cultures, carrying out the provision for such unnatural deaths was considered a filial obligation and a way of according honor to the parent rather than evidence of rejection or neglect. However, it is likely that these traditions were implemented only under situations of dire stress. In many hunting societies the aged, ill, and weak often found aid and support, not only from their own kin but also among groups of strangers, each group providing aid in recognition of its own nomadic members' possible future needs.

The stable family units of agrarian and herding societies are better able to care for the aged. Relatively well to do rural families could in the past, even as now, care for aged incompetent parents in special wings or in small cottages removed from their main house. And the well to do could then, as now, exhort the poor to follow their example in honoring their fathers and mothers, although for the poor this was and still remains economically and socially impossible. In this way families may be encouraged to pursue programs of protective care that can destroy family units or overburden inadequately prepared communities.

Even before the advent of industrialization, social pressures in urban centers resulted in the development of havens or hospitals for the care of the aged, the ill, the weak, and the socially disturbed who required protection and care. In Western culture, religious groups have been important in developing homes and hospitals; their example of what was good and helpful has more and more been adopted as governmental responsibility; what was first offered as a charity has become, in many parts of the world, a responsibility of government and a legal right.

Social welfare has become progressively more necessary with increasing industrialization and urbanization of society. However, at the present time many subcultures of our society still provide examples of almost every historically identifiable way of handling the problems of the aged. Examples of masked euthanasia, family care, care by neighbors or unorganized community, and varying degrees of private and public welfare concern can be found in this country, side by side.

Special Problems of Old Age

A chronologically aged healthy person usually behaves and has needs that do not differ greatly from those of younger persons. He desires friendships of varying types and intimacy with both sexes. He wants to keep busy at work or at play that is within his physical capacities and is commensurate with his intelligence and background, and from which he derives a sense of accomplishment. He looks for and objects to frustration of relief of biological tensions, such as hunger and sexual desire, and the gratification of culturally determined needs.

Ideally, an aged person has confidence in his capacity to relieve his tensions and obtain gratification in a culturally acceptable manner, and he maintains a continuity with his past in terms of interest, goals, and gratifying pursuits. In contrast to the young adult, he may put less emphasis on current performance and more on self-assurance that he has made an impression on this world in his lifetime by his words or his deeds or by having reproduced himself. Review of past achievements or the behavior of children or disciples can contribute to his self-esteem. Unlike young people, he may show mellowness—a lack of haste, a patience with himself and others, and a tolerance that has grown out of satisfied curiosity. Most important, he appears to have internalized the values of his culture so that he continues to be capable of playing the various roles required by his achieved or ascribed status. Ideally, he has been and is a rational, considerate, cooperative, self-reliant, self-disciplined person able to gain pleasure through his own efforts and with others; he has few complaints and is minimally complained about.

This ideal, however, is rarely achieved. In chronological aging there is usually a decline in function of one or another organ or system. This may be the result of genetic factors, illness, or accident. Furthermore, there may be changes in the environment or in the person's social role for which he is psychologically unprepared. Such changes may reveal a paucity of resources for adequate functioning even in someone relatively intact; when he is also physically ill or mentally impaired, and especially if he has developed incapacitating psychological inhibitions, his capacity to adapt successfully may be so grossly inadequate that he becomes inefficient, disturbed, and socially disturbing.

Before true old age becomes manifest, the chronologically old may suffer loss of social and economic resources and may apprehensively anticipate physical and mental decline. Those with psychogenic disorders only are, as a rule, relatively energetic and vigorous. Unless they are specifically ill, as with cardiac or malignant disease, they usually have a better outlook for survival than the debilitated and frequently incapacitated aged in whom psychogenic disorder accompanies an organic mental syndrome.

Their mental disorders are frequently similar to those found in younger persons, are fully as responsive to treatment, and are as liable to aggravation by neglect. In fact, their late emergence is an indication of the relative hardness and resistance to psychopathology of the afflicted; however, this may be neutralized or outweighed by special social, economic, and health hazards in aging that predispose to stress and increase vulnerability.

Resources useful or necessary for the mastering of internal or external problems are diminished or lost with aging. Simultaneously, the person may be faced by new and unexpected actual or potential stress. There may be physical or psychological decline, loss of family and friends, loss of status or occupation. Losses of one type may be related to others with snowballing effect: loss of physical strength and skill may lead to loss of occupational status, this to change of environment because of retirement, this to loss of friends and associates and sometimes to removal from family. The loss of personal resources and the stresses imposed by the environment decrease the individual's ability to adjust successfully to his changing environment, to relieve tensions, and to satisfy his biologically and culturally determined needs. With these losses and changes, old quiescent mental disorders may be revived, persistent disorders aggravated, latent disorders revealed, or new reactions developed.

Physical and physiological losses. Many physical changes in the aged are the result of illness; others appear to be the effects of the aging process itself. As medical knowledge increases, more of the functional decline associated with aging is attributed to disease and less to genetically determined processes. The genetic contribution to aging, however, appears to be strong. As Pearl showed, the life span of an individual can be fairly accurately predicted from knowledge of the ages of his parents and grandparents. The sum of these ages he called the index of Total Immediate Ancestral Longevity (TIAL). Marked longevity is associated with a high score. Undoubtedly, genetically determined life-shortening or life-preserving factors interact with environmental influences to determine the individual's life span.

Physical changes include decreased sensory acuity, decreased executive capacity because of diminished motor strength, changes in bodily appearance that affect social and economic role and status, and decline in central nervous system integrative efficiency.

Visual defects or blindness affect about 4 per cent of persons in their early sixties but about 15 per cent of persons in their eighties. Hearing impairments are present in about 5 per cent of persons in their sixties and in at least 25 per cent of these in their eighties. Taste suffers because of the decrease in the number of taste buds. Smell may also become less acute. Not only sensory loss but sensory disturbances may occur: small hemorrhages in the brain stem may cause equilibrium difficulties; glandular alterations may cause drying of

the skin and contribute to feelings of heat or formication.

Gross decline in motor strength of the aged is evidenced by paralysis in about 1 per cent of persons at age 60 and in over 3 per cent of those aged 80. Osteoarthritis is an extremely common condition that severely restricts the mobility of many old persons. Following strokes, weakness short of paralysis is frequent. Loss of muscle mass, decreased elasticity of connective tissue, osteoporosis, and spontaneous fracture of the hip with its limiting sequelae are common. The shortening of steps, bowing of spine, and shrinking of torso may induce troubling changes not only in the attitudes of other persons but in the aged person's attitude toward himself.

In neuromuscular disabilities, the interweaving of somatic and mental disorder and the emotionally determined exacerbation, exaggeration, aggravation, and exploitation of illness is especially notable. It is often difficult to determine how much of a disability is the result of impairment in neuromuscular and skeletal systems or pain and how much is related to ignorance, fear, and depression.

Cardiovascular and respiratory diseases obviously also curtail activity.

Reactions to physical, chemical, and living assaultive agents are often impaired. The decreased defensive and healing capacity affects the interaction of persons and assaultive agents so that diseases are masked—the aged person feels and is more ill than signs may suggest.

Physical losses and losses in central nervous system integrative capacity after brain damage undoubtedly contribute to the high accident rate of the aged; these accidents, in turn, make a large contribution to the physical impairments of old age (see Figure 3).

Physical illness and death. The anticipation of illness, pain and suffering, and death—the ultimate loss of powers and the final loss of the things and the persons they have loved, watched over, and derived pleasure from—constitute serious psychological problems for most persons.

The relationship of health and psychological reactions is complex. Childhood experiences with ill health, parental and social attitudes toward the sick person, the time of life in which these illnesses occurred, and the type, severity, and duration of illness all undoubtedly influence self-evaluation, control of self, feelings of fragility or vulnerability, and tendencies to utilize or exploit illness. With aging, individuals may react to illness or debility with feelings of helplessness and fear. Many persons in their sixties become significantly depressed when ill, and depression frequently precedes and heralds the existence of a somatic disorder. Moreover, latent illnesses such as glaucoma, diabetes, and hypertension may be exacerbated. Progressive cardiovascular disease, with its recognized threat to life and the functional

limitations it imposes, may provoke fear, anger, and depressive reactions. Conversely, emotional overreaction can aggravate previously mild cardiovascular, endocrine, and other disease processes.

Disability commonly exceeds what the impairment would seem to justify. Exploitation of illness by a frightened person is common. Persons who appear to have healthy personalities, who have been and continue to be relatively assertive, active, and interested in youthful pursuits and social interchange, tend to evaluate themselves as happy and symptom-free and have an optimistic outlook on life, even in the presence of obvious impairment and ill health. Well-adjusted aged persons think of the old as capable, active, energetic, and flexible, even though their own physical condition belies such a view.

Physical alterations in appearance and strength may constitute real losses in assets for persons whose occupation or social and domestic success depends on seeming youthfulness of face, figure, or movement. The same may be said for changes in performance and capacities for self-gratification. For some persons, these changes in appearance, energy, and stamina provoke fears, anger, and self-hatred; disease may even provoke shame or feelings that this is punishment for past behavior or current attitudes toward others. Obviously, psychological reactions to aging and illness complicate the effects of the changes in structure and function. Some persons aggressively deny illness or aging and attempt to continue all previous activities; others, in fright or resentment, excessively limit themselves.

Social and economic losses. Personal, social, and economic losses or changes are important factors in the emergence of mental disorder in the aged. The loss of family or friends, social position, money, residence, or occupation all have adverse effects.

To the aging person, retirement, for reasons of health, business policy, or desire for leisure, often means a change in role and a decrease in social status and prestige. With retirement and cessation of wages, self-regard and sense of purpose may evaporate. Changes occur in interests, attitudes, and values as environmental demands, new ascribed role, and decreased opportunities for individual achievement affect the person's status and activity.

Socioeconomic factors affect the development of the individual from earliest years. The socioeconomically deprived appear to be less well prepared to tolerate the adversities and changes of old age than those with more nurturant, educational, and occupational advantages. Economic security appears to be an important factor in the maintenance of morale in old age. Income from savings, pension, or Social Security benefits are not only smaller than previous income but also progressively devaluated by the unceasing inflationary trend, adding financial hardships to psychologically traumatic experiences. Poor aged persons who have achieved a measure of economic security

FIGURE 3. Accident death rate (nonautomobile) for male and female. (From *Vital Statistics of the U.S.*, vol. 1, United States Department of Health, Education, and Welfare, Washington, 1959.)

appear to be less anxious, angry, and depressed than those who are dependent on relatives and an uncertain income. Persons who are financially well off appear to have higher morale and are less prone to display chronic affective disorder than poor persons.

Certainly, good adjustment in old age is only partially attributable to economic security; such security generally reflects good opportunities early in life, which have resulted in greater personal, social, and economic resources. Nevertheless, economic resources appear to take precedence over most others as a supportive factor in old age. The influence of economic security on morale and as a counter to depressive reaction appears to supersede even physical status. In short, from the point of view of good spirits and social integration, it appears that in old age it is better to be rich and sick than poor and healthy.

Family and interpersonal relationships. As people grow older, their families and friends become preoccupied with their own problems, change jobs, move, become ill, age, or die. Often, their families can be neither socially nor economically helpful. If not themselves aged, their children are likely to have families of their own. The nuclear family of comparatively young parents and children is relatively mobile, lives in small quarters, and is separated geographically from the grandparent generation. In addition, both husband and wife generally work, out of necessity rather than for luxuries. Consequently, the

burden of protection, supervision, or residential care for aging or aged parents is shifted to community organizations.

Contrary to popular notions, aged persons who live with or see family members frequently are not necessarily happier or freer of psychiatric disturbance or less lonely, blue, or bored than aged persons who live alone and seldom see their families. In fact, the converse is often true; living with one's family or making frequent visits to them may be evidence of financial need, illness, or anxiety on the part of the aged rather than of family solidarity and cohesion. Loneliness and boredom of aged persons cannot be regarded as causes of psychiatric illness; rather, they are symptoms of a recognized or unrecognized affective disorder in which the aged person is yearning for and attempting to gain a special protected relationship with a child or another parental surrogate. A distinction can be made between the aged isolate—one who can pleasurably live alone—and the aged desolate—one who, having lost family or friends, remains inconsolable or desperately in need of replacements.

Sexual losses. In both men and women, change in appearance and loss of sexual value may pose serious problems. Men are often severely troubled by loss of potency, which was not only a source of pleasure and a fancied way of rendering service to a woman and guaranteeing her interest but also a symbol of masculinity and worth as a person. For a woman, loss of sexual attractiveness may threaten her feelings of security in a marital relationship, although she may welcome the decreased sexual interest of her mate. In both men and women, the decline of sexual interest and activity appears to be related to early acquired sexual habits and interests. The timid, prudish, and inhibited tend to welcome loss of sexual powers and drive and to limit activity or lose sexual capacity earlier than those who have been active and relatively uninhibited. Therefore, one partner may tend to refuse the other by saying, "You (or we) are too old for that."

Adaptation to losses. In general, it appears that persons who retain a youthful, vigorous, problem-solving view of life tend to make a better adjustment in old age than those who accept old age as a time of diminished resources and agility or of relatively stereotyped behavior. Persons who, although themselves chronologically aged, feel that the aged do not need protection but are likely to be healthy or socially vigorous are relatively well adjusted, even when their own physical status and socioeconomic condition belie their conviction.

Persons who have had a self-assertive, problem-solving approach to life tend to be less hypochondriacal and less prone to depression in old age. Even when they become ill, they have fewer complaints and tend to be less depressed by their physical illness. In contrast, the relatively nonassertive, more passive persons complain more and, although greatly in need

of people, are generally less well integrated socially. This is not to say that dominating, domineering, or controlling persons make a good adjustment in old age. Many persons manifest their need for others during maturity by gaining and holding them through overly compassionate mothering or socially accepted directive behavior. These people are not self-assertive; they are, rather, aggressive persons whose personality constriction is partially compensated for by controlled anger. In old age such persons, on removal of children or when widowed, complain of loneliness and boredom. These complaints, which are evidence of their fear of being alone and without a guaranteed protective person, may be masked by controlling oversolicitude with children, grandchildren, or friends.

Many of the losses of aging affect men more adversely than women. Women, unless severely disabled, can usually retain their roles as housewives and remain useful, or seemingly so, until late in life; furthermore, for women the successful maintenance of relationships is usually more important than work performance or earning money. This is probably why they can adjust better than men to the loss of friends and family, occupation, material objects, or their accustomed living quarters.

Personal, cultural, socioeconomic, and physical changes probably contribute to mental disorder, invalidism, alcoholism, and accidents in old age and undoubtedly contribute to the high suicide rate of aged white males (see Figure 4). The differing suicide rates of males and females and of whites and non-whites probably reflect socioeconomic conditions, differential survival into old age, and culturally determined patterns of reaction. The suicides in old age appear to be directly related to ill health and depressive reactions and not so much, as in younger persons, to clear cut interpersonal difficulties and unstable personalities.

From the foregoing, it is clear that money, social position, supportive persons, psychological adaptability, and physical health protect the aged from stressful circumstances and from the emergence of patterns of intrapsychic and externally obvious behavioral disturbances. The decrease or loss of such resources for adaptation provokes or permits the emergence of maladjusted, inefficient behavior called mental disorder. Physical changes, especially those following illness and those affecting the brain, may have great influence on the individual. At times, however, economic adversity, loss of family or friends, and changes in their attitudes have greater impact. The relationship of physical, psychological, social, and economic resources to the preservation of good functioning and mental health is shown in Table I.

Dependency. As previously noted, illness, accidents, and genetically determined processes contribute to the loss of resources, diminish adaptive capacity, and complicate previously existing deficits. The newly lost resources can be categorized as: (1) physical:

health, strength, and appearance; (2) psychological: cognitive and emotional; (3) social: family, friends, associates, avocations, prestige, social status, respect, utility, and personal acceptability; (4) economic: property, income, or gainful occupation.

Loss of any of these resources is capable of evoking grief or depression. Running counter to these losses and protecting against the depressive reaction are such factors as special skills, prestige, financial position, legally or socially vested powers, and the special interest of family, friends, or society, based on previous relationships and cultural attitudes.

For most aged individuals, the loss of resources is added to already limited resources for adaptation. Those that chiefly interest the psychiatrist are the deficits in adaptive capacity based on psychological inhibitions—fears—that are usually acquired early and are modified, reinforced, and elaborated in the lifetime of the individual. Not only have these inhibitions limited the person's capacity to act self-assertively, productively, and creatively, but they may have interfered with formal learning and with profiting from experience. Frequently, ignorance or failure to acquire efficient adaptive techniques is the result of lack of opportunity to learn, because of socioeconomic deprivation in early life or social neglect.

When protective or compensatory factors are outweighed by the losses of aging and the preexisting limitations, the individual anticipates or experiences failures in mastering the problems and challenges of everyday life. This leads to feelings of helplessness.

FIGURE 4. Suicide rate by age, color, and sex in the United States in 1959. (From *Vital Statistics of the U.S.*, vol. 1. United States Department of Health, Education, and Welfare, Washington, 1959.)

TABLE I
Contributors to High Morale: Factors Which
Counteract Depression*

Factor	Protective Device	Protective Effect	Result
Relative affluence	Economic security: food, shelter, services, mobility, medical care	Freedom from fear and anger	Limited need for family and friends
	Physical security: power, physical comfort, pleasure	Assertiveness	
High educational level	Well established mechanisms of psychological, social, and emotional adjustment	Self-confidence Self-esteem Self-direction: interests and purpose Sense of identity	Responsiveness to needs of family
	Diversity and range of interests		
Social status	Social security	Social independence	Capacity for solitary self-enjoyment
Good health	Power Mobility Physical comfort or pleasure Physical security	Physical independence	Ability for independent productive or pleasurable activity

* From Goldfarb, A. I. Responsibilities to our aged. *Amer. J. Nurs.*, 64: 64, 1964.

For most persons in this society, feelings of helplessness are unpleasant and frightening. Helplessness and failure—real or anticipated—decrease self-esteem, sense of worth or dignity, and confidence. Activity becomes restricted, and purposiveness decreases. Anger often becomes mixed with fear and is accentuated by limitation of ability to master everyday problems, to achieve relief from tensions, and to provide oneself with gratifying experiences. Anger is often directed against oneself for being damaged, a failure, helpless and worthless—further decreasing self-esteem and self-confidence. Anger is also directed against persons and natural processes that appear to be increasingly harsh and threatening as the individual becomes progressively impaired or weaker. At times anger adds to feelings of strength and permits mobili-

zation of the remaining resources, but expression of anger usually leads to increased fear because of guilt, conviction that one should be punished, and a realistic fear of retaliation (see Figure 5).

Fear and anger occasionally mobilize the person to relatively efficient action, thereby decreasing feelings of helplessness, fear, and anger. However, emotional overreaction usually tends to disorganize action, thereby decreasing efficiency. In this setting of cyclically increasing fear, anger, and helplessness, the person's need for others becomes accentuated. He looks to others for assistance, aid, or emotional support (see Figure 6).

FIGURE 5. The intrapsychic evolution of disturbed and disturbing behavior in the aged.

This search for aid and support is a manifestation of the dependent state in which an individual who regards himself as weak and in need of assistance strives to find another he believes to be strong to assist him. His efforts become devoted to searching for or gaining such actual or promised assistance and to maintaining this relationship. This search for aid is sometimes transparently clear, but more often it is complex and obscure; the person hides it from himself and others. It is revealed by the person's conversational flow and his behavior toward family members or potentially helpful persons. The search for aid is, in essence, an attempt to make someone else be something he is not or do something he cannot and to have him remain in the desired gratifying role and relationship. The patient's search for another presumed to be stronger and capable of helping and the maneuvers to hold the other in a helpful or potentially helpful relationship are sometimes called dependency or dependency striving.

Individuals who feel helpless and in need of assistance can seek aid in a rational, constructive manner while also displaying inefficient, irrational behavior.

For example, a physically impaired or ill aged person could seek out a physician and cooperate with him to eliminate or ameliorate a disorder. This does occur with many older persons. More often, however, the individual's search for aid is primarily irrational, even when the rational elements are present. That is to say, there is a search for emotional support; the person seeks evidence to convince him that aid is promised, can be called on, and will be made available by the delegated protector.

A belief that such a person's aid or powers have been gained permits the individual to feel secure on illusory as well as on substantial grounds. This, un-

fortunately, renders him susceptible to charlatans, faith healers, and quacks for the same reasons that he may improve under the care of skilled physicians who provide effective aid through therapeutic use of the self in an easily fostered, controlled therapeutic relationship. The protector or recipient of the dependent person's love can be called a parentified person, and the patient's pleas for understanding or love are, in effect, a turn toward a delegated surrogate parent figure. Unsophisticated persons can mistake their delegation to special status by the patient for real love and make misguided psychotoxic responses based on their own needs, fears, or resentment. The patient's verbal and nonverbal behavior usually tells the physician what attributes and powers the patient desires in the parentified person. These serve as clues for the physician to what he should not do, lest the patient becomes disillusioned, unnecessarily disengaged, or harmed.

Common Psychiatric Conditions of Old Age

Almost all the mental disorders found in younger persons can persist into or recur in old age. Schizo-

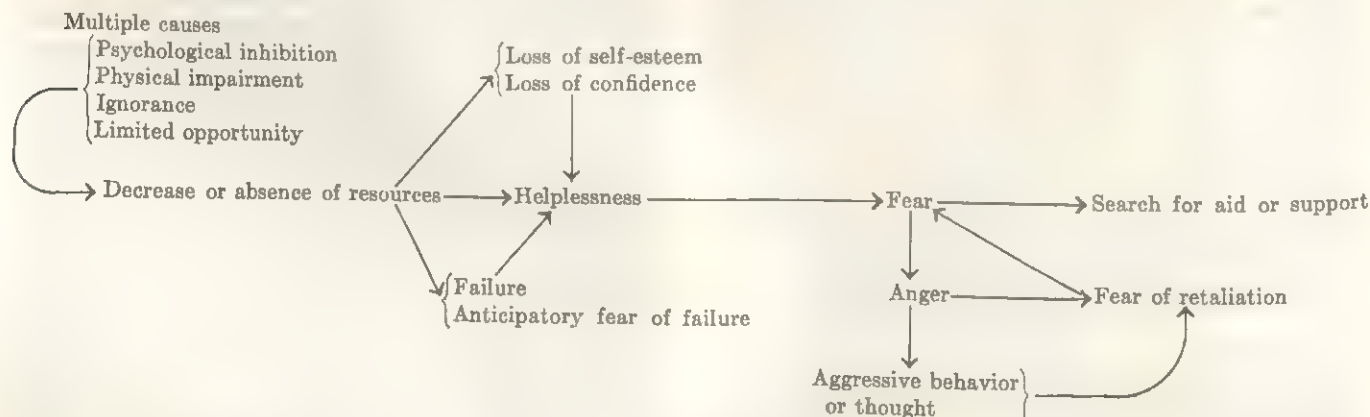

FIGURE 6. Elaboration of Figure 5.

phrenia, manic-depressive psychoses, involutional psychoses, drug dependence, alcoholism, and the organic mental syndromes are common mental disorders in old age. The physician must be familiar with the various patterns of all these disorders and recognize their continuation or periodic exacerbation in old age. Although these traditional diagnostic categories can help orient the physician with respect to prognosis and treatment, such categories are too broad in that they obscure individual differences and too restrictive in that they appear to be mutually exclusive and chronic.

Current official classification systems can be regarded as nosological groupings that are determined by medical fashions at the time of coinage, and their use is biased by the training and predilections of physicians or by the immediate goals of therapy. They are not of great value in geropsychiatry. As stated succinctly by Post in 1962, "In individual cases the psychopathological picture [can] change from a depressive to a schizophrenic one," and in 1964, "Subdivision of affective disorders into those due to cerebral-organic changes, involutional processes, and endogenous, constitutional, and reactive psychogenic causes has a low scientific status." Traditional classification may identify only the well advanced, well crystallized biologically and culturally determined expressions of fear, anger, and appeals for aid.

Some of the preexisting well crystallized personality patterns or ways of life to which classical diagnostic terms can be applied take on new significance or first emerge as troublesome to patient or family when circumstances and personal attributes change with aging. In addition, physical, social, and economic losses and challenges that frighten, anger, and depress the individual may evoke florid neurotic and grossly disordered behavior that frequently defies classification.

Because of these multiple contributions, mental disorder is very common in old age. Any of these syndromes may be further complicated in old age by the simultaneous presence of organic brain disorders.

Organic brain disorders. Differentiation between the purely or chiefly organic disorders and the psychogenic disorders is of value in prognosis and in formulation of treatment plans. Moreover, emotional and psychological factors may be of primary importance in the prevention of mental symptoms, even when brain damage is present.

"Brain syndrome" is the term applied to the group of measurable defects of mentation that reflect brain damage or dysfunction. When these deficiencies are transient, the condition is called acute and is thought to reflect reversible cerebral disturbance; when the deficiencies persist, despite adequate environmental and medical corrective measures, the condition is deemed chronic and is ascribed to brain damage. The older the patient, the more likely it is that brain damage plays a part in the genesis of behavioral

disorder, but chronological age should not be used as a diagnostic criterion.

Signs of brain syndrome. Brain syndrome consists of the following characteristics: (1) Disorientation for time, place, or person. (2) Evidence of impaired immediate recall. (3) Deficits of recent and remote memory. (4) Weakening of intellectual functions, as indicated by difficulty and errors in doing simple calculations or in recalling simple items of general information. (5) Defects of grasp and comprehension. These defects may be indicated by difficulty in retaining and reacting to questions or commands. They may also be indicated by faulty reaction to a situation or an interpersonal transaction, revealing that it is not understood. This can be called situational disorientation. (6) Intermittent or persistent occurrences of the above, as shown by a reliable history from the patient or other sources.

In the absence of stupor, coma, catatonia, excitement, complete deafness, marked language difficulty, or other factors that make examination impossible or its results questionable, the first four signs are diagnostic of brain syndrome. In chronic brain syndrome, one of these deficits is rarely found without the others, although some may be less obvious or severe than others. If only one or several of the signs are found, developing brain syndrome may be suspected. The diagnosis of chronic brain syndrome is best made only when all of the first four signs are present, even if only to a slight degree.

Other presumptive signs include emotional lability, focal neurological signs—including aphasia, agnosia, and apraxia—slovenliness or poor habits, poor judgment not clearly related to emotional disturbance, and apathy. When these signs appear to be irreversible and related to brain damage, as opposed to brain dysfunction of a reversible or transient nature, the condition is termed chronic.

Acute brain syndrome. This is a transient and potentially reversible condition that is usually related to an acute febrile, debilitating, or exhausting illness. There is often evidence of dehydration or malnutrition. Common conditions provocative of acute brain syndrome are malnutrition; infection; pain; fractures; heart failure; coronary thrombosis; drug intoxication; malignancy; electrolyte imbalance related to diuretics, vomiting, or renal disease; and emotional overreaction. In the aged, however, fever, tachycardia, leukocytosis, or obvious physical signs may be absent even with acute illness. This may lead to a mistaken diagnosis of chronic brain syndrome. Blood count and chemistry, urinalysis, and physical examination give clues to reversible disorder by revealing acute illness. Anemia, nutritional history, or a history of drug ingestion often point to the etiology of the disorder.

With acute brain syndrome, all the signs of brain syndrome are not necessarily present simultaneously. There are usually fluctuations in degree of disorienta-

tion, misinterpretations, and occasionally hallucinatory phenomena. At times the disorder may be quiet; at other times it is characterized by restlessness, helplessness and bewildered confusion, or a tendency to wander, both physically and verbally. In some cases, as an exaggeration of preexisting chronic brain syndrome, the disorder can attract attention to underlying or developing illness, signs of which may or may not have been noted previously.

In almost all cases, the existence of acute brain syndrome in the aged may be taken as presumptive evidence of the simultaneous presence of developing chronic brain syndrome. Attacks of acute brain syndrome often contribute to a steplike progression of the more chronic form. Whenever there is an episode of acute brain syndrome, attempts should be made to determine whether chronic brain syndrome is also present.

Chronic brain syndrome. Diffuse brain damage appears to be necessary for the emergence of signs of chronic brain syndrome. Single episodes of cerebral thrombosis, hemorrhage, or embolism appear to give rise to signs of focal rather than diffuse damage, unless there is cardiovascular, pulmonary, or other systemic disease that contributes to generalized cerebral damage through influence on blood supply or metabolism. The effects of expanding intracranial lesions when cerebral intercranial pressure is high and decompensation is occurring or when the lesions are multiple may be mistaken for cerebral arteriosclerosis in aged persons. The concept of functional neuronal mass may be helpful: brain syndrome can be considered to have emerged when functional neuronal mass has been decreased to a critical point. Patients can evidence many strokes before the emergence of brain syndrome, despite signs pointing to foci of brain damage.

The patient with cerebral arteriosclerosis and focal damage is usually acutely aware of loss of physical and mental powers and reacts to his losses with feelings of depression, a common reaction to severe or threatening illness of any kind. Depression is especially notable in those whose personal integrity is threatened by the effects of brain damage. Attempts to repair, ward off, or defend oneself against the threat of disintegration are occasionally abetted by anosognosia, in which the patient does not know and knows not that he knows not. Under such circumstances, even such gross physical defects as hemiparesis may not be attended to, admitted to, or come to the patient's awareness.

Senile brain changes are presumed to be etiological factors in the production of chronic brain syndrome when there are no focal neurological signs and when there is no history of stroke. This disorder usually begins after, rarely before, age 65; it is more common after age 70 and is almost universal in the eighties. It is often insidious in onset; its progression may be introduced by vaguely defined emotional disorders

and, at times, by clear cut depression. When diffuse brain damage develops slowly and environmental circumstances are supportive or when there is a minimum of stress, the individual may be able to compensate for functional loss with relatively little emotional upset. Depressive reactions even in very late life, therefore, should not be dismissed as secondary to brain damage or cerebral arterial sclerosis.

With brain syndrome due to any cause, good education, high occupational and economic status, and the early acquisition of socially acceptable patterns of behavior tend to protect against troublesome behavior. There may be excellent preservation of function, especially on a social level, despite severe brain syndrome. Social behavior may be so well preserved as to mask severe memory deficit and disorientation.

The brain damage which leads to the emergence of brain syndrome may be the end result of many factors. Chronic brain syndrome in some persons appears to be the result of genetically determined cerebral deterioration, in others the result of extracerebral or intracerebral arterial vascular disease, and continued or episodic cerebral malsupport such as can elicit symptoms of acute brain syndrome.

Old classifications of patients as having senile dementia, senile psychosis, or cerebral arteriosclerosis with psychosis may place undue emphasis on organic factors and lead to neglect of opportunities to improve behavior and decrease suffering. Clear differentiations should be made between the degree of organic impairment present, and changed behavior, alteration of mood, disorganization of thought or action, and the type of intensity of distortion of thought content and behavioral disturbance present (see Figure 7). The alterations of mood, content, and behavior may be complex, motivated, goal-seeking—albeit painful, inefficient, and socially disturbing—elaborations that require a certain minimum of cerebral competence that is absent in persons with severe brain syndrome. Persons with mild or moderate degrees of brain syndrome may generate severe affective or paranoid reactions; persons with severe brain syndrome may display agitation or disorganization of behavior but do not appear to have the cerebral cortical wherewithal to elaborate recognizable affect or content.

Chronic brain syndrome may be considered mild when defects of general information are present but memory and orientation are relatively good. It can be called moderate when calculation, memory, and general information are impaired but orientation is fair or good. It is severe when there are obvious defects of orientation and of memory and intellectual function.

Disorientation can be considered mild when the patient can recognize and name friends or persons in the family correctly, answer the question "Where are you now?" and correctly give the year, the month, and the approximate day of the month. Disorientation is moderate when the patient almost always correctly

FIGURE 7. A diagram showing the variety of factors lying behind acute or chronic alterations of brain function. Etiological factors may act singly or in combination, slowly or rapidly, continuously or episodically, once or repeatedly, to result in dysfunction or damage. Individual personality patterns the measurable organic mental syndrome with respect to what is more or less selectively forgotten, retained, or attended to. Brain malfunctioning or decreased functioning may itself contribute directly to mood, content, and behavioral disturbance; but it is the person's previous personality which, in reaction to the impairment, the social situation, and the probable future, has the more important influence in the production of "psychotic" characteristics.

identifies persons, but only approximately identifies or locates places and cannot give the correct year, month, and day of the month. Disorientation is severe when the patient misidentifies persons, incorrectly names and locates places, and cannot give the correct year, month, and day. When disorientation is severe, chronic brain syndrome can be considered severe.

In rating the severity of chronic brain syndrome, the psychiatrist may be helped by 10 questions that test for orientation, memory, and ability to do simple calculations. The questions are: (1) Where are we now? (2) Where is this place located? (3) What is today's date, day of month? (4) What month is it? (5) What year is it? (6) How old are you? (7) When is your birthday? (8) What year were you born? (9) Who is President of the United States? (10) Who was President before him?

The mental status questionnaire, when scored in terms of number of errors made, correlates well with psychiatric estimates of degree of brain syndrome, as shown in Table II. This correlation, of course, is expected because the questionnaire is a standardization of the items generally used in arriving at the psychiatric judgment.

This approach to the diagnosis of brain syndrome is admittedly somewhat rigid. Many clinicians feel that the diagnosis of organic mental syndrome, specifically that of cerebral arteriosclerosis with psychosis, is justifiable even in the absence of disorientation or memory loss. They base their opinion on the fact that the disorder can be considered a postcerebral thrombosis reaction type, in which social judgment is impaired, emotional lability is present, paranoid ideation is common, and depressive or hypomanic behavior may emerge as highly troublesome and resistant to treatment. However attractive it may be, this concept that affective disorder is a stage in the development of an organic mental syndrome in old age is not supported by careful clinical observation. Affective disorders can, however, be precipitated or aggravated by a stroke or by emergence of brain syndrome in predisposed persons.

In addition to a brief mental status questionnaire, double simultaneous stimulation of the cheek and the dorsum of the hand may yield information confirma-

tory of brain damage. The test is performed with the patient's hands on knees, facing the examiner, who says: "I am going to touch you. Please tell me or point to where I touch you. Close your eyes." The examiner then simultaneously touches, or brushes lightly, the cheek and dorsum of the hand on the right side, then the left side, then one cheek and opposite hand, and then the reverse; each time asking for a report of where a touch has been felt. This is followed by simultaneous stimulation of the two cheeks and of the two hands; these are considered "teaching trials" in that these are almost invariably reported correctly by even severely brain damaged persons, provided they are testable. Following these two teaching trials the patient, if free of brain damage, usually reports a repetition of the first four trials without error. If errors are made the test is repeated with the eyes open; it is of interest that about 80 per cent of persons who make errors with eyes closed tend to do so with eyes opened. The errors made are almost invariably failure to report correctly the stimulus to the back of the hands. There is either extinction, reporting the stimulus to another part of the body, or pointing to the hand of the examiner or into space. The examiner must be aware, however, that like all tests it must be understood within the context of other findings. Manic or depressed patients who are unable to attend may make errors unrelated to brain syndrome unless the test is patiently and carefully administered.

TABLE II
Rating of Functional Impairment by Mental Status Questionnaire^a

Number of Errors	Presumed Mental Status
0-2	Chronic brain syndrome absent or mild
3-8	Chronic brain syndrome moderate
9-10	Chronic brain syndrome severe
Nontestable ^b	Chronic brain syndrome severe

^b In the cooperative person without deafness or insuperable language barrier.

Functional disorders

Schizophrenic reactions. The chronologically aged with schizophrenic disorders can be subdivided into three categories. In the first are the persons who are in psychiatric hospitals. Many of these persons have made a good hospital adjustment and can be adequately cared for in exceptionally well run nursing homes or foster homes if there is adequate psychiatric supervision. They get along equally well in hospitals organized as small communities. Other patients have deteriorated to such an extent that they require constant close supervision and care in a hospital setting. The large scale removal of persons with mental illness who require long term care to nursing homes has been advocated. This may solve financial or administrative problems, but it cannot now be considered a preferred treatment method. Nursing homes are not themselves capable of providing the community setting for social and occupational integration that a well organized psychiatric hospital can provide, nor are they part of the larger community.

A second category of persons are recognizably ill but, with family and community support, have remained socially integrated. Among these persons are some whose special skills or attributes serve to protect them from social and economic difficulties that would make hospitalization necessary.

A third group are persons in whom paranoid or other symptoms are well handled by the person or are so unobtrusive that they have escaped notice until old age. Many of these persons are considered arrogant, eccentric, or suspicious. Among them may be included the paraphrenic persons described by Roth. In many, hearing defects appear to reinforce or trigger the development of paranoid symptoms. Also in this group are chronologically old persons who have become mentally impaired, physically weak, or, in men, sexually impotent and who develop angry, paranoid ideas that usually focus on the spouse or family. In men, especially those with prostatism or postprostatectomy, delusions of the wife's infidelity are common. Women often complain of being spied on, subjected to stimulation by concealed electrical appliances, or poisoned by fumes sent under the door. In general, the paranoid symptoms appear to be related to preoccupation with physical decline or discomfort; they provide clues to what frightens the person and reveal what he wants from the persons around him. Paranoid symbolic representation of discomfort with serious and frightening illness is common. For example, a man with rectal carcinoma complained that "men in the cellar are causing trouble" and wanted someone to deal with them.

Aged persons with schizophrenic symptoms of any kind tend to respond well to phenothiazine drugs. Medication must be judiciously administered so as not to reduce marginal cerebral competence by direct drug action on the nervous system or by lowering blood pressure. Chlorpromazine and thioridazine appear to be

most effective and best tolerated. Electroshock therapy is not of great value; although response may be more immediate, it may be a spurious improvement with memory loss. Recovery of memory may result in reemergence of the disorder or relapse.

Affective reactions. Persons with manic-depressive psychoses can be categorized as those who are in the hospital; those who, although ill from youth, remain socially integrated; and those in whom the disorder has escaped attention in youth but emerged as troublesome in old age.

A large number of persons with affective disorders remain effective in the community, despite alternation of depressive and hypomanic or relatively well periods. With aging, the disorder may become more regular and predictable. Some persons have shorter or more rapid alternating episodes; in others, the episodes become longer, and there is no true free period. A large number become chronically depressed. It is doubtful that age ever brings with it a relief from such symptoms.

Persons with depressions generally respond fairly well to antidepressant drugs. As is true for the phenothiazine group, these medications—amitriptyline, imipramine, and the monoamine oxidase inhibitors—must be carefully supervised. Electroshock therapy is of greater value than the antidepressant drugs only in depressive reactions in which vegetative signs are minimal and agitated and belligerent behavior is prominent. The use of prophylactic electroshock treatment is of doubtful value. Leukotomy has been recommended by some European authorities, but it appears to be unnecessarily drastic. Recently, lithium salts have attracted attention as of value in manic states. If begun in the manic or "well" intervals, regular daily oral administration of lithium carbonate (about 500 mg.) may reduce the severity of the manic symptoms and both shorten and decrease the intensity of the depressive episodes, with eventual almost complete subsidence of the disorder. This drug is not yet released for general use. The patient should be carefully watched for signs of low blood sodium and potassium.

Involutional psychotic reaction. The existence of involutional psychotic reaction as an entity has been legitimately questioned. Nevertheless, there does appear to be a special subgroup of mental disorders worthy of special classification. This subgroup is characterized by depression, hypochondriasis, low self-esteem, guilt (especially about sexual behavior and desire), with self-deprecatory and self-accusatory trends (especially about sex and sinfulness), often associated with florid paranoid ideation and behavior. In women who have had emotional reactions temporally related to their menstrual cycle, there is often an emergence with aging (but not necessarily related to sexual involution) of prolonged tension, depression, and paranoid trends similar to those that periodically occurred in the past. In both men and women in whom mental disorders become prominent in middle age or later life, the prognosis when paranoid ideation is present is not

as good as when such ideas are absent or are very clearly secondary to depression or elation.

Pseudoneurotic affective or mood-cyclic disorder. With the advent of old age or life-threatening physical disease, many persons begin to review their past with feelings of regret; they feel that they have failed to achieve cherished goals, to make adequate use of their assets, or to realize their potential. They are grieved and depressed by the loss of a potentially viable self, much as is a woman after an abortion, but less consolably so, for they feel there is no second chance.

Clearly affective disorders that closely resemble the involuntional psychoses are often incorrectly categorized as organic mental syndromes when they occur in chronological old age. At first glance, many appear to be first depressive episodes, but a careful history often reveals that they are actually exaggerations of prior symptoms. The previous episodes or symptoms had either gone unnoticed or had been considered an aspect of psychoneurotic behavior, periodic hypochondriasis, or recurrent exacerbation of such physical disorders as arthritis. In retrospect, many of these persons appear to have been suffering with pseudoneurotic mood-cyclic disorder. Some of these prior episodes may have been recognized as depressions and classified as involuntional.

In the past, electroshock therapy was regarded as specific for these disorders. Now, there is disenchantment with respect to its efficacy as increasing experience attests to the recurrent nature of these depressive reactions of middle age and early old age, and the relative uselessness of attempting to differentiate between endogenous or reactive, mood-cyclic, involuntional, and neurotic affective reactions. It is probably best simply to differentiate between affective disorders with prominent, typical vegetative signs and disorders of affect with few or no such signs.

Manic and hypomanic disorders. Although less frequent than depression, these disorders are nevertheless common in old age. The patient and his family frequently fail to recognize the hypomanic phase of mood-cyclic disorder. They may regard it as a period of well-being, despite the presence of aggressiveness, overactivity, and poor judgment. The afflicted persons are usually hostile or paranoid, often accusing a specific close person, such as the spouse or child. The family may regard this behavior as an exaggeration of previous characteristics and unpleasant disposition rather than as a phase of illness. Treatment or hospitalization may be sought only when the disorder threatens the family's physical, social, or economic welfare.

When excitement is prominent, these disorders may be mislabeled agitated reactions or be mistaken for dementia. Their resolution sometimes results in their being called, in retrospect, states of pseudodementia. They usually follow a depressive reaction which may have been so brief as to escape attention. They may be mixed with depression and invariably include paranoid

trends. They may occur in compulsive, relatively passive persons after a frightening illness or bereavement or in anticipation of loss, as by the marriage of a child. The response to treatment is good; phenothiazines alone, followed by the addition of antidepressants as the manic behavior subsides, are usually effective. Electroshock therapy is of no great long term value. Lithium salts have been suggested for recalcitrant cases and, as previously noted, show promise.

Alcoholism and drug dependence. Alcoholism is probably the most common form of drug dependence. Aged alcoholics who pose psychiatric problems are usually found among the younger segment of the old-age group. For the most part, they are individuals who began to drink in youth or middle age. Their health, habits, and circumstances have been such that, despite alcoholic excesses, they have survived into old age. Included in their ranks are many divorced men, widows, and men who never married. When called to medical attention, they are often persons who have no families or who have left or have been abandoned by their families because of their poor social and occupational adjustment. Many are in the lowest socioeconomic groups.

The preponderant number of aged persons who reach prisons are excessive drinkers whose arrests for vagrancy are directly related to alcoholism. Without work, income, or helpful family, they tend to spend more time in jail awaiting trial—for they can muster no bail—and serving short sentences than they do in the world outside.

The contribution of alcoholism to accidents and suicides in old age is not known. Much more information about the genesis, development, and course of this disorder in old age is needed; it has not yet been adequately studied either medically or psychiatrically.

Excessive alcohol intake, poor nutrition, and concomitant illness frequently cause acute brain syndrome. When this happens or when the alcoholism is complicated by physical debility or aberrant behavior, medical treatment or hospitalization is required. These persons have a good prognosis for the acute episode and for discharge from the hospital; therefore, many have repeated hospital admissions until the development of chronic brain syndrome makes long term care necessary.

The management of the excessive drinker is complicated by poverty, inhumane social and legal attitudes, and a dearth of facilities. For the aged alcoholic who has socioeconomic supports, management depends on the willingness of the individual to enter into a supportive relationship with a physician or other persons who can be of assistance in regulating his behavior and helping in the resolution of personal and situational problems. Prolonged institutional stay is often required for adequate treatment of the physical and psychological disorders.

Dependence on drugs such as hypnotics and narcotics is probably more common in old age than is

generally known. Many aged persons are habituated to sleeping pills, and some insist on regular doses of sedatives for chronic pain. Hypochondriasis is at times partly determined by the aged person's dependence on a favorite medicine. Tonics and similar nostrums are more often prized for their alcoholic or sedative content than for their otherwise generally inactive ingredients.

Psychoneurotic reactions. Almost all the psychoneurotic syndromes seen in younger persons can be carried into old age. With the advent of brain syndrome, they often emerge so floridly that they simulate psychotic symptoms. Especially prominent psychoneurotic manifestations are frank anxiety, depression, the exaggeration or exploitation of actual illness, and physical or mental impairment in the pattern of conversion psychoneurotic reactions; but phobic and obsessional syndromes are also carried into old age. Obsessional preoccupation with detail and compulsive cleanliness are frequently misinterpreted as the cantankerousness and finicky behavior of the aged. Psychoneurotic traits appear to be exaggerated by depression and improve with treatment of the affective disorder.

Psychophysiological reactions. As with psychoneurotic reactions, many psychophysiological disorders are carried from youth into old age, but some seem to improve or burn out. It is possible that many persons who suffer severely from the psychophysiological disorders do not survive into old age. Nevertheless, persons with asthma, spastic colitis, and peptic ulcer are found among the aged. Within a well organized home for the aged, persons who have been admitted with such disorders tend to improve markedly during the period of their residence. It is possible that institutionalization answers their needs for total care, which lends strong support to concepts that emphasize the importance of dependency striving or ungratified dependency needs in their genesis and of emotional overreaction and depressive states in the perpetuation of such disturbances.

Other disorders, such as diabetes, hypertension, and glaucoma, may be accentuated in the presence of a depressive reaction. Vigorous treatment of depression can have such a salutary effect on these conditions that the use of drugs seemingly contraindicated by the pathophysiology is clearly indicated. Thus, amphetamines may, paradoxically, help reduce blood pressure and tachycardia through amelioration of the depression, and amitriptyline may result in decreased intraocular tension for the same reason. Diabetes usually becomes more severe and more difficult to manage with depression. The first appearance of diabetes may signal the onset of a depressive reaction; psychic improvement may convert frank diabetes to a latent or milder form.

Anorexia and constipation are common in the aged. Like insomnia, they are almost invariably associated with depression. Contrary to popular belief, aged persons need more, not less, sleep than do young adults.

Sleep disturbances are pathognomonic of psychic disturbances in the aged, and complaints about insomnia are a clue to a need for psychiatric attention.

Miscellaneous conditions. A variety of depressive syndromes are difficult to classify. They are found either alone or—because depressive reactions can occur in schizoid, retarded, or otherwise mentally impaired or ill persons—in association with other mental disorders or as concomitants of physical illness. All functional mental disorders may be regarded as part of a continuum. According to this scheme, the disorders or syndromes of the maladjusted aged are viewed as motivated goal-seeking appeals for aid within a social transaction. Depending on circumstances and environmental response, variations of a search for aid can be displayed by different persons or by the same person at different times. The variations are patterned according to the values and beliefs of the individual, his view of culture, and the social response to his behavior.

A patient may be openly frightened or brave, ingratiating, seductive, belligerent, coercive, withdrawn, or pseudoanhedonic—all with appropriate subjective dynamics as circumstances appear to require. Even late developing depressive reactions, manic-depressive, paranoid, and schizophrenic syndromes can be viewed as struggles between the patient and his social environment. In all, the patient appears to be attempting to manipulate others in a context of misunderstanding. Even when he appears to be withdrawn and apathetic or violently hostile, the patient may be attempting to gain assistance or emotional support from those about him or from a desired special other person of his fantasy.

Treatment

Because many of the aged are physically or mentally impaired or have limited socioeconomic opportunities, the physician must be prepared to limit his treatment goals and yet be wary of personal predilection or social persuasion to give up too easily. Treatment of mental disorders in the aged requires that attention be paid to more than the patient. Not only the complaints of the patient but those of his family, the community, and the persons charged with his care must be attended to. The need for treatment is often indicated when the disorder creates a family or community disturbance.

The physician must be certain that any acute or chronic medical condition of the patient is recognized, that action is taken where indicated for the amelioration of pain, and that acute brain syndrome is reversed through specific and generally supportive medical care. Furthermore, the presence and degree of chronic brain syndrome must be ascertained in planning the type and goals of treatment.

In general, the goals of treatment are to decrease the patient's suffering so that he has a minimum of complaints; to improve his behavior and decrease interpersonal friction so that he is minimally complained about; to increase his capacity for making and

retaining friendships with persons of both sexes and for socially acceptable sexual behavior; to restore him to work or an equivalent avocational activity within the limits of his remaining resources and commensurate with his intelligence, training, skill, and customary social role; to motivate or remotivate him; to evoke a desire to act so that he is maximally productive and creative. When a patient is motivated or remotivated and takes part in what he feels is meaningful and effective problem solving, there is accompanying pleasure through successful action. He regains a sense of purpose and identity.

To reach these goals, the physician can aim specifically to decrease the patient's actual or felt helplessness or his fear and anger. In some persons, the fear or anger that arises at the beginning of treatment may cause action that decreases the sense of helplessness. Subsequent feelings of guilt, fear of retaliation, and resentment may be useful in directing behavior along socially and personally acceptable lines. Although the warning and inhibitory actions of emergency emotion can often be utilized, emotional overreaction usually grossly disorganizes behavior; its unfavorable effects on self-confidence and self-esteem are particularly undesirable. Self-esteem and self-confidence must be fostered and restored; the patient's motivation to do and to succeed must be heightened; he must be encouraged to develop purpose and interest. When he acts and has a goal, his sense of who he is and what he is and where he is going—his sense of identity—is reinforced or restored.

These goals and aims can be achieved by a variety of techniques. Psychotherapy, occupational or avocational activity, group or individual therapy, and drugs or physical methods all have as their effective common denominator motivation and organization of behavior within the framework of a personal relationship.

Whatever the vehicle for psychotherapy, the psychiatrist starts by regarding the patient as having become bogged down in his own ineffective attempt to recoup losses and to compensate for weakness. He has become increasingly helpless, frightened, and angry because of continued failure. He is caught up in a search for aid or support. The psychiatrist responds to this search by permitting the patient to regard him as the sought for surrogate parent. He refrains from discouraging the patient's tendency to delegate him as such and to take pride in his ability to interest the physician. With patients who have socioeconomic and personal mobility, the physician can help the patient gain insight, learn new techniques, and make helpful major changes in patterns of action and life situation. In the care of the aged, however, especially the mentally or physically impaired, the gains must often be limited to what the patient derives from the reassuring and supportive relationship.

Traditional classification is of limited aid in prognosis and treatment. Not only is it difficult to differentiate between neurosis and psychosis, but it is not

always clear how one can differentiate between the types of psychosis in the aged. A psychodynamic and psychosocial construct in which dependency and helplessness are central is of help in structuring treatment plans. Hypochondriacal or paranoid trends commonly present themselves first in disorders of mood, depression or elation accompanying or alternating with angry, accusing, or frankly paranoid ideation. With elation, there is commonly seen an underlying or alternating depressive trend, and depressed persons often behave in an expansive, grandiose manner. Such paradoxical behavior has its roots in the patient's conviction, on the one hand, that the experience or display of suffering will gain and hold the desired protective, helping person and, on the other, that a show of power and worth will win the desired protector. For the individual, behavior he believes may gain aid carries with it a sense of relief and joy. The distressed patient, even as he feels scared and in pain, may feel more secure and more powerful because he is feeling and performing so as to gain help. In many persons, self-aggrandizement and self-confident behavior are utilized consciously or automatically to impress, please, gain, and hold the desired and needed support.

Milieu. The debility of the aged and their need for nursing make the use of hospitals, special nurses, or attendants imperative for many and useful with others. As at any age, hospitalization may prove to be a beneficial removal from disturbing home circumstances and relationships, can provide a salutary regimen, can offer protection to the person with suicidal or assaultive thoughts or behavior, and can afford rest and relief to the family. In addition, the well equipped hospital offers many opportunities for therapeutic relationships with staff members, and its various occupational, vocational, psychiatric, and other ancillary medical services are potential vehicles for psychotherapy. Medical care itself, over and above its specifically beneficial effects on physical health, has an important psychotherapeutic effect, usually based on the patient's conviction that he has obtained the aid of the omnipotent helpful parental equivalents.

Although they are most frequently seen in private practice, clinics, or general hospitals, many aged persons with depressive, paranoid, and other psychiatric syndromes find their way into old age and nursing homes. The successful treatment of these institutionalized aged persons requires that basic services be adequate and competently administered. In the absence of proper nutrition, housing, and good medical care, the more subtle and sophisticated ministrations are of little value. In the provision of these basic medical services, the paramount importance of the patient-staff and patient-doctor relationships can never be ignored. In Rado's words, one can inflict pain but not pleasure. It is possible to contribute to the patient's comfort and to avoid the infliction of pain, but it is impossible to force pleasure on him; this must be elicited and be given opportunity and encouragement

to emerge in and by way of the relationship with staff members and as the patient recognizes his own success.

Psychotherapy. The patient-doctor relationship is basic to good psychiatric care, whether in or outside an institution. In some conditions it is the primary treatment; in others it seems to help the patient to begin and sustain the salutary medical regimen.

The psychiatrist should be prominently eligible for selection and delegation as the parental surrogate. As such, he attracts and impresses, not because of his personal attributes so much as because of what the patient is looking for and predisposed to see. Someone has said, "A psychiatrist should not be impressive; if he is, it should appear to be camouflage." The patient must be able to read into the person what he wishes to find and needs to believe is there. For this reason, certain persons appear to be more eligible than others to fill the required role.

Selection or delegation is made by the person according to his acculturation and experience. For middle class persons, a physician, psychiatrist, member of the clinic staff, institutional administrator, or any person who has access to these powerful figures, such as their secretaries or assistants, may be parentified. The designated person may permit himself to appear to be appraising and evaluating the patient vis-à-vis; it is often useful to let it seem that some effort on the patient's part is required to gain the therapist. Therapists who appear indiscriminating may be regarded as unworthy by the patient. But this situation should never be threatening; delegation should not be obstructed because the therapist is too hard to get. The delegated role must be accepted. Clues given by the patient are used to avoid violating the illusion that he has found the desired and needed person. At times the therapist must allow himself to be made a target for punishment. This permits guilt and fear to arise in the patient, which prompts him to improved behavior; at times the therapist may provide "token punishment," but only where necessary to keep behavior within tolerable bounds and to forestall self-punitive expiatory action and to provide a quasi-parental figure consonant with his needs. The therapist should recognize the symbolic nature of the patient's complaints and be guided by the need expressed but appear to deal only with the reality situation the patient presents. Similarly, the therapist should recognize that somatic complaints and querulousness are signs of depression but, as far as the patient is concerned, he must appear to accept them at face value while discouraging unnecessary and possibly harmful treatment. He may help the patient verbalize anxiety and discuss its seemingly rational origins or usefulness, but he must not join the patient in his fears. He must regard complaints as justified without encouraging tendencies to exaggerate or exploit. Above all, the patient must be permitted to believe that the therapist has accepted his delegated role because of the patient's personal worth, skill, attractiveness, or other good qualities. The patient may be

permitted to believe he has tricked the therapist, triumphed over him, or gained him by "strength of character." The patient must be permitted to believe that the therapist is the friend, ally, and powerful servant he has been searching for.

Figure 8 lists some of the more commonly reported subjective complaints and clinical observations of mentally ill aged persons. This list is not all inclusive but may serve to illustrate how the variations and intensity of signs and symptoms may be useful in deciding on type of treatment and improvement regardless of nosology.

In the second column of the figure are listed some symptoms and signs of disorders, usually categorized as psychoneurotic, in which the therapist-patient relationship is of primary importance.

In the third column are listed the relatively mixed signs and symptoms usually regarded as "psychotic," and the more severe signs of these disorders are listed in the last column. Especially troublesome behavior in the last column usually indicates a need for hospital care and may require electroshock therapy to avoid exhaustion or accidents.

Pharmacotherapy and physical methods. It is a rule of thumb that medication is helpful in the development and maintenance of a therapeutic relationship with persons who have few or no vegetative signs, whereas persons often regarded as psychotic, in whom the physical concomitants of depression are relatively severe, require a good patient-doctor relationship to ensure adherence to the drug regime (see Table III). Drugs suggested for the symptomatic and relatively specific treatment of mental disorders can be classified as antidepressants, tranquilizers, sedatives, hypnotics, analgesics, vitamins, hormones, and vasodilators.

Antidepressants and tranquilizers. The search for aid may itself be called a depressive syndrome; however, it may be elaborated in a manner that calls for antidepressant medication, tranquilizing medication, or both. When sadness, guilt, and self-depreciatory or self-punitive behavior are obvious, the depressive aspects may attract attention and determine the classification. The choice of medication is best made on the basis of whether or not a shift in physiological equilibrium, measurable by sleep and gastrointestinal function, has occurred. Diurnal mood change, early morning waking, anorexia or bulimia, and constipation or diarrhea are signals that depressive rumination and depressive affect have encompassed or are being determined by a physiological shifting of gears to a special and abnormal homeostatic level, for which electroshock treatment or the antidepressant drugs are helpful. Such illnesses are generally self-limited and recurrent, but the duration and course of the illness in a person who has had no previous attacks are not usually predictable.

Until recently, the only reliable treatment that decreased suffering and shortened disorders in persons who had vegetative signs with depression was elec-

Symptom	Mild	Moderate	Severe
Evaluation of problems	"Difficult"; "feels nervous"; "can't cope with problems" Would like or yearns for help or relief	"Life a struggle" Feels urgent need for help; pleads, commands	Problem overwhelming Desire for complete care or riddance; suicidal thoughts or acts; homicidal thoughts or acts
Energy and activity	Fatigability; normal or decreased activity	Lethargy or restlessness; hyperactivity	Retardation or agitation; incessant hyperactivity
Interest	Loss of interest; decreased desire "to do"; slow start in morning, afternoon good; desire to do better	Inaction; all day bad, evening fair; envy of others who "do"	Apathy; purposelessness; relief just before or only with sleep; bitter self-recriminations, envy and hatred of others
Concentration	Impaired	Poor; preoccupied	Completely unable to concentrate to highly distractible
Mood	Subjective malaise; joyless; blue, low	Active discomfort; unhappy; sad	Painful depression; apathy; pseudoanhedonia; painful misery
Sleep pattern	Longing for rest Longing for night; longing for sleep Unable to fall asleep or early waking Bedtime worry	Frequent recourse to couch Late out of bed Very early waking with rumination Rumination about problems	Remains in or returns to bed by day Very early waking with agitation, tension, and rumination Rumination about "this illness"
Gastrointestinal	Poor appetite Digestive distress	Anorexia or bulimia Constipation	Nauseated, revolted by food; hypochondriacal delusions Obstipation
Weight loss in previous 4-12 wks.	None	0-5 lb.	5-15 lb.
Self-esteem	Low	Self-deprecatory	Self-accusing, guilt-ridden; convinced has done serious harm (last two rare in aged); feelings of worthlessness; self regarded as "poisonous" and containing poison; conviction should be eradicated
Self-confidence	Low	Feelings of failure; helpless	Completely helpless, ineffectual, incapable
Somatic complaints	Somatic preoccupation; somatic fears	Hypochondriasis; fear of death	Somatic delusions; conviction of impending annihilation
Interpersonal or social behavior	Indecisive; "can't make up mind" Asks advice, looks for help Complaints about others or another; distrustful	Puzzled, "don't know what to do" Denies complaint; acts out search for aid Blames others or another; suspicious	Bewildered; "confused"; <i>déjà vu</i> ; depersonalization (last two rare in aged) Clinging, demanding; insistent or commanding; coercive, assaultive, suicidal Accusing; ideas of reference; feeling of passivity and manipulation; delusions of persecution; threatening hallucinations
Fear/anger	"Anxious," worried; irritable	"Afraid," angry; sustained fright and anger	Intensely frightened, panicky, enraged

FIGURE 8. Symptomatic guide to treatment. These are listed in terms of social impairment, disturbing quality, and subjective distress. The *solid lines* in the diagram enclose conditions in which antidepressant drugs are usually helpful. The *broken lines* enclose symptoms and signs in which phenothiazines are often useful. The conditions enclosed by *both solid and broken lines* are those in which the combination of antidepressants and phenothiazines is usually indicated. For the symptoms *not included in the broken or solid line areas*, a variety of sedatives or stimulants may be helpful.

troshock therapy. Now there are medications—the tricyclic compounds and the monoamine oxidase inhibitors—that are fully as effective or better for most persons. Amitriptyline (Elavil) is the most useful of the tricyclic drugs, and imipramine (Tofranil) is almost as good. Phenelzine (Nardil) appears to be the best of the monoamine oxidase inhibitors for use in the aged.

Amitriptyline and imipramine are best started in

divided doses of about 40 to 100 mg. a day. This can slowly be increased by the addition of 20 to 50 mg. every 2nd or 3rd day to 125 mg. a day in small or debilitated persons, or in the more robust to 250 mg. a day, as tolerance to the medication increases and until depression decreases. A dose of 250 mg. a day is not unusual for persons in the 7th decade. They may also benefit from the simultaneous administration of small amounts of dextroamphetamine sulfate, which serves

TABLE III
Autonomic Dysfunction as a Clue to Therapy

	Physician-Patient Relationship	Pharmacotherapy
Mild or no vegetative signs	Primary	Secondary
Vegetative signs	Secondary	Primary

to decrease subjective depression more immediately and serves to maintain blood pressure.

Dextroamphetamine sulfate in doses of from 1.25 to 2.5 mg. in the morning, at noon, and at 3 P.M. can give a boost early in treatment to patients receiving a tricyclic compound, which works more slowly, but it is most useful after 2 to 3 weeks to help break through plateaus. It is also useful in patients whose prominent symptoms are fatigue, lack of initiative, and poor spirits. Its value is enhanced by combination with 8 to 15 mg. of amobarbital. Methylphenidate (Ritalin) has been advocated as of similar value, with the claim that it is less likely to elevate blood pressure or evoke tachycardia, but it appears to have no real advantage. Like dextroamphetamine, it should be given in small doses of 1 to 2 mg. These medications appear to prime or energize the individual in the fashion of epinephrine and, like the tricyclic compounds, act by favoring sympathetic as opposed to parasympathetic autonomic nervous system tone.

For agitation, excitement, hypomanic and manic disorders, chlorpromazine (Thorazine) and thioridazine (Mellaril) appear to be most effective. Small amounts may be sufficient; therefore, 10 mg. of either drug given four times daily may be a starting dose. This can be increased rapidly to 200 mg. or more each day as need and tolerance suggest. However, patients with marginal cerebral competence may become confused with even small doses and may tolerate promethazine (Phenergan) best; 12.5 mg. of this may be given two to four times daily. The prophylactic use of anti-Parkinson medications with phenothiazines is unnecessary; these drugs complicate matters because of their agitating effects and their tendency to promote paranoid ideation. Lithium carbonate promises to be an effective "tranquilizer." While this is still in the experimental stage, it seems that from 125 to 250 mg. given once or twice daily, monitored by plasma levels during the first 3 weeks of administration so as to keep under 1.5 milliequivalents per liter, will bring agitated, excited, and hyperactive states under control within a period of days or weeks; phenothiazines and antidepressants may be used conjointly. Toxic symptoms resemble those of heat stroke; low salt and low potassium levels were reported from unsupervised, indiscriminate use of lithium as a salt substitute. Discontinuation of lithium, urging fluids, and supplementary NaCl and KCl, by mouth or vein, correct the toxic state. Special caution is required in the presence of cardiac or renal disease.

Sedatives and hypnotics. As previously noted, aged persons need more, not less, sleep than young persons. Lack of sleep and rest may be a cause of mental disorganization and complication of an affective disturbance. The correction of insomnia is, therefore, important, but insomnia of the early morning waking type is not substantially improved by hypnotics, and only relief of the depression is effective in improving sleep.

Sedatives and hypnotics have little effect on the manifestations listed in the last column of Figure 8. Their action is usually good for complaints such as those listed in the second column and only sometimes for those listed in the third column. One must rely on antidepressants or phenothiazines and wait for their effect, and not expect barbiturates, meprobamate (Equanil, Meprospan, Miltown), chlordiazepoxide (Librium), or diazepam (Valium) to be of real assistance in these more severe disorders.

The older drugs, warm milk, warm baths, and a soothing atmosphere may be of value in contributing to rest and sleep in disturbances listed in the second and third columns. Paraldehyde now has limited use because it is distasteful to both patient and attendants. The new tranquilizers can be useful in small doses as sedatives; in larger doses, distributed throughout the day, they may help dispense with medication for sleep at night without unduly hampering behavior or alertness by day.

Chloral hydrate (Noctec, Somnos) is a safe hypnotic but is not preferred to the barbiturates. Barbiturates especially the shorter acting ones such as pentobarbital sodium and secobarbital (Seconal), are generally useful and more effective for patients in whom kidney and liver functions are good. When kidney function is good, phenobarbital in small doses can safely be used. Amobarbital is especially useful in agitated persons. In persons with early morning waking, these medicines are best given when the patient awakes at night, to decrease the anxiety and rumination, rather than at bedtime. Seemingly healthy aged persons may develop signs of brain syndrome with small doses of barbiturates; this suggests that cerebral competence is marginal. In such persons there is generally a fine line between the amounts of medication that may quiet, agitate, or render stuporous.

The use of a compound containing reserpine in any amount is to be discouraged. Reserpine appears to have little real sedative value and is commonly a contributing cause to delayed—6 or more months later—depressive reactions.

Analgesics. Pain may give rise to fear and disorganization of thought and behavior. An aged woman who agitatedly claimed she was being persecuted and that her eyes were endangered was found to have glaucoma. Another who insisted on constantly searching for a slipper was found to have a painful plantar wart. On another occasion, she complained about her stocking and was found to have a painful phlebitis of the

calf. In addition to required specific treatment, relief from pain is indicated as a means of controlling the emergence of florid psychopathology in frightened persons with reduced or marginal cerebral competence.

An analgesic, sedative effect may be obtained from 10 to 15 grains of acetylsalicylic acid with 5 grains of soda bicarbonate, or as buffered aspirin. Dextropropoxyphene (Darvon), 32 to 64 mg., may also be helpful.

Vitamins. Aged persons may subsist on a poorly prepared, monotonous, inadequate diet because of frugality, debility, poverty, poor memory, or lack of interest in cooking for oneself. Fresh fruits and vegetables are among the first foods to be neglected by the aged who succumb to poor diet habits. Nevertheless, supplementary vitamins are of limited value in psychiatric disorders of the aged except when malnutrition is present with depression or brain syndrome.

Nicotinic acid deficiency, as is well known from the dementia of pellagra, may contribute to cerebral mal-support and to reversible brain syndrome; up to 500 mg. one to three times daily may have a mild energizing, helpful alerting effect. Thiamine chloride and ascorbic acid for a week or 10 days at initiation of treatment may be helpful for persons who have brain syndrome and associated disorder. Thiamine chloride has a mild sedative action, is a mild stimulant to appetite, and is a substance that under stress tends to be depleted in the adrenal cortex, where it has essential metabolic action. A dose of about 200 mg. daily appears empirically useful. Ascorbic acid also appears to be essential to adrenal cortical function. It is rapidly depleted with stress and poor nutrition; 200 to 500 mg. daily are ample doses for replacement and maintenance.

Hormones. Hormones have little use and play little part in the treatment of psychiatric disorders of the aged. This is so despite the fact that some women in their sixties still complain of hot flushes, night sweats, and malaise. For them, small doses of estrogen or estrogenic substances can be helpful. However, the value of these preparations is greatly overrated, and their ability to provoke or accentuate depression is greatly underestimated.

The use of testosterone in the male as a tonic agent is probably more often effective because of the recipient's powers of imagination than for its physiological action. As an anabolic agent, testosterone alone or in combination with other medications may be of minor value. In some persons it appears to affect appetite and weight beneficially. Testosterone is best administered orally as methyltestosterone; 10 mg. daily for about 1 week, then every other day for about 1 week, and less frequently thereafter is ample dosage. The injectable propionate is less effective.

Female hormones, when used in males with prostatic carcinoma, may induce mild depressive reaction, which clears with discontinuance of the medication. Whether the depression is at times a reaction to the patient's knowledge of the disorder for which the hormone is

prescribed, to accompanying surgical procedures—prostatectomy or castration—or to feminization of habitus is not clear. Probably all factors play a part, some with greater force in particular persons than others.

Alcohol. The cocktail has become an American subcultural custom; for those accustomed to it, it has its value prior to the evening meal. For hundreds of years small amounts of spiritus frumenti before meals have been advocated as a tonic for the aged, to be given as such or masquerading as the vehicle for some relatively inert tonic. This use is decidedly limited in psychiatry, as is its traditional use in the form of champagne for its value in decreasing gastric discomfort through the effect of its carbonation. Carbonated water is cheaper, and cola drinks are sweeter.

Side effects. The patient may tend to incorporate side effects of medications in his symptom complex, complicating the emotional disturbance. A good patient-doctor relationship permits neutralization or even beneficial use to be made of the side effects. In the aged, one must be on the alert for hypertensive crises, which can occur paradoxically, and also for the development of hypotension, which evokes brain dysfunction and threatens brain damage due to poor cerebral support. The antidepressants also appear to have direct cerebral action which may induce or exaggerate symptoms of brain syndrome.

The patient may be asked to regard harmless side effects such as drowsiness, blurred vision, and dry mouth as evidence of favorable drug activity. Drowsiness usually disappears in a few days in patients who will be favorably affected by tricyclic drugs; its persistence may suggest trial of another. Blurred vision usually persists and must be tolerated. Dry mouth also persists and is greatly accentuated by mouth breathing and talking; increased fluid intake is of no value and may accentuate peripheral edema. Lemon peel or other salivary stimulants chewed or held in the mouth and frequent rinses can be helpful. Swelling of the ankles, if mild, sometimes responds well to the judicious use of diuretics. Drug reduction may be indicated. A welcome side effect in most aged persons is the tendency of the tricyclic drugs to decrease urinary frequency and nocturia. It is of interest also that, with lifting of depression, many men who have awakened in the night to void, presumably because of prostatism, no longer do so. This does not appear to be entirely a direct drug effect; the benefit sometimes persists upon drug discontinuance.

Although glaucoma is listed as a contraindication to the use of the tricyclic compounds with anticholinergic action, the action of these drugs upon the depression appears to have a favorable effect upon intraocular tension which often outweighs its possible dangers. Ophthalmological supervision may be increased and extra amounts of miotics prescribed as a precaution. Because many hypotensive agents in medical use are monoamine oxidase inhibitors, a careful history of

prior and current treatment is especially necessary before beginning treatment of depressed hypotensive persons. Other medication taken should be reviewed and careful use of or discontinuation of antihypertension agents is recommended when antidepressants are administered. Dietary precautions—against fermented cheeses and wine with monoamine oxidase inhibitors, and with respect to alcoholic beverages with phenothiazines—are in order.

Evaluation of improvement. Criteria for improvement in disorders of affect in the aged are, in the main, the same as for younger persons. Notations of restoration to previous norms of sleep, appetite, and bowel function are of special importance because these are matters about which the patient, nursing personnel, and physician can make relatively objective determinations.

Like younger persons, the aged patient with depressive reactions is drowsy and falls asleep in the evening, wakes before bedtime, falls asleep without any trouble, and then tends to wake in the early morning hours. The patient yearns for sleep, looks forward to it, and may retreat to bed during the day. On waking in the early morning, he may ruminate and have feelings of anxiety, worry, and heaviness. In the aged, instead of worry there are frequently feelings of malaise, restlessness, empty concern over the depressed feelings, and a desire to feel well. Improvement can be measured by the patient's tendency to wake later in the morning until he finally wakes at the previous customary time. This improvement is facilitated by decreasing drowsiness in the evening, by elimination of evening naps, by decreased eagerness and yearning for night and the relief that comes with the unconsciousness of sleep. The lifting of depression is also signaled for some by the return of dreaming, which is reported as entirely absent during the depth of the depression.

Restoration of appetite to the previous norm is also an indicator of recovery. The usual pattern with depression is anorexia. As depression lifts, food, which was repellent or repulsive, can be better tolerated; people who could not eat become able to do so because they know they should. Later, they begin to feel a little interest in the food and begin to feel hunger. Lastly, appetite returns. Accompanying this there tends to be a restoration of weight lost with the anxiety, depression, and anorexia. A significant proportion of depressed aged women have bulimia and preoccupation with food; as their depression lifts, the compulsive overeating tends to decrease. As might be expected, the individual then eats in a less driven manner but with more enjoyment and, consequently, may even become capable of following a regimen helpful for the loss of the excess weight.

Bowel function is usually reduced with depression, and constipation may be severe. Spurious diarrhea may occur with fecal impaction. As the depression lifts, previous regularity of bowel function is restored. A

number of depressed persons have persistent or intermittent diarrhea. With lifting of the depression, this also tends to improve spontaneously.

The reports of subjective sadness or its equivalent in terms of malaise, somatic discomfort, or inertia also offer an index of change. With improvement, these symptoms decrease toward the end of the day and then are felt less intensely progressively earlier each day as recovery takes place. Before relatively complete recovery, only the early morning hours remain bad. The patient may describe the subjective sensations of depression in the morning simply as "heaviness" that tends to disappear or lessen after dressing or having breakfast. With the decrease in these symptoms, there is usually an observable decrease in psychomotor retardation or its equivalent, agitation. When a depression is communicated solely in terms of somatic complaints, which is very frequent in the aged, these are worse in the morning and tend to decrease in their intensity as the day wears on.

Decrease in rumination and change in paranoid complaints also occur as the depression lifts. Depressive complaints and paranoid trends may change inversely. With decreasing depression, attacks of a paranoid type on a mate or attendants may increase markedly. This leads to a paradoxical social situation. The quiet, meek, unobtrusive, or clinging depressed patient may be preferred by family or staff to the angry, accusing, complaining, aged patient seemingly free of depression. Conversely, the paranoid elaboration of the hypomanic or manic patient as he becomes more calm may give way to considerate, clinging, and somewhat depressed behavior with response to treatment. Alternating expression of this type is common. Commonly patients feel jealous of all persons who are not sick and may express this in an irritable, querulous fashion. Thus, an increase in irritability and querulousness may indicate improvement or worsening of depression. In some persons, paranoid ideation and expression of paranoid ideas become more marked as the depression lifts, appearing at first with greatest force toward the end of the day; they may increase to take in more of the day and eventually, especially if the person moves into a hypomanic or manic state, be continuously present. Paranoid complaints may take the form of angry verbal attacks on the environment or may be somatically expressed in terms of great suffering with implicit or explicit accusations about the neglect or the faults of others. Or, as is most often the case, they may take the form of accusing and obvious diatribes and remarks about mates, children, relatives, and friends.

In institutionalized persons, such accusations invariably include members of the nursing and attending staff. Such paranoid ruminations or conversations are often complicated by belligerent behavior in the recovery stage. Many patients do not move from this stage of high nuisance value into relative normality but return to depressive reaction. Thus, the improve-

ment of depressed patients often converts a meek, mild, ingratiating or retarded, docile, manageable individual into a vociferous, annoying, accusing, and troublesome individual.

Somewhat similar to diurnal variations are changes in the week. For some individuals, such as housewives, the weekends may be the worst if they mean involvement with otherwise absent family or the absence of individuals they especially turn to. For some workers, such as teachers, weekends may be best because they mean relief from tasks that emphasize their poor concentration.

Improvement in concentration and concomitant capacity to do things, which are lost with depression, are useful measures. Ability to attend to the conversation of others, to follow radio or television programs, to read with understanding, in that order, improve with the lifting of depression. The capacity to concentrate on tasks follows increase of capacity to receive and process communications. At first, the person is merely able to do simple manual work of a mechanical or stereotyped nature; then he becomes able to do tasks of increasing complexity. Eventually, appetite for pursuits of various types returns, and initiative, previously strikingly absent, is restored to its former level.

In general, symptomatic and behavioral changes do not mean that the condition or process of affective disorder has been permanently arrested. Relapse or recurrence is common. This is true whether the treatment has been solely or predominantly psychotherapeutic, pharmacological, electroconvulsant, or inclusive of environmental change and education.

Prognosis

Affective disorders tend to be self-limited, and spontaneous recovery can be expected in the preponderant number of afflicted persons. The duration of the illness is always problematic, suffering can be intense, and physical or social complications can be serious. Therefore, active as compared to expectant treatment is always preferable. Prompt and effective treatment to decrease the suffering and shorten the course of the disorder is especially important in the aged because of their increased vulnerability to exhaustion, physical damage, and death. Even when brain syndrome is simultaneously present, treatment to improve mood, thinking, and behavior can be effective and may decrease the severity of disorientation, memory loss, and intellectual deficit.

As in younger persons, the aged patient's outlook for improvement in behavior and for social adjustment appears to be related to his past performance and personal characteristics; the present circumstances, including the availability of family members; and the rapidity of onset and floridity of symptoms. Some specific characteristics of the patient when he comes to medical attention permit fairly reliable prediction of outcome for the immediate illness.

For aged patients with affective disorders, the outlook is best when they are under 70 years of age, are in good physical health, have a history of good recovery from prior attacks in middle age, and have no signs of brain syndrome. A history of mood-cyclic disorder in parents or siblings is also favorable. Relatively acute onset of the disorder and seemingly clear precipitating events, such as a surgical operation or financial reverses; florid symptoms; and a rapid response to the initiation of treatment are further favorable signs. Despite favorable outlook for immediate recovery, the outlook for affective reactions in the aged is poor under optimal circumstances because recurrence is the rule. Advanced age at onset of the first attack; the presence of debility or incurable physical illness; and the coexistence of brain syndrome, especially if it is severe, are especially unfavorable signs. Also unfavorable is a history of prolonged, insidious onset or long standing illness—2 years or more—prior to initiation of treatment.

The good prognosis of hypomanic or manic persons may be obscured because they often present a superficial picture of dementia. However, a careful examination will reveal that their errors are due to poor attention, distractibility, and circumstantiality. The outlook for recovery of such persons is usually good, and their improvement may astound those who have mistaken the affective disorder for the disorganization of behavior that occurs with severe brain damage. Doubtful cases should, therefore, be treated as affective disorders, since neglect may lead to exhaustion or physical illness and provoke the condition for which it has been mistaken.

Rapid response to electroshock therapy should be interpreted with caution. With this treatment, depression, elation, or excitement may be controlled before the underlying condition has substantially improved because of the effect on memory or because the patient is rendered relatively inert and unable to express emotion. If treatment is prematurely interrupted, apparent relapse may occur when memory is recovered or is restored. Because many of the aged have slim cortical resources and may become confused by relatively few electroshock treatments, there may be early spurious improvement. Furthermore, electroshock therapy may yield early symptomatic improvement but not lasting improvement because it interrupts or stalls the disease process before the necessary time has elapsed to achieve a physiological shift. Thus, there appears to be a relapse 3 to 6 weeks after apparent recovery with electroshock therapy. Resumption of treatment, either electroshock therapy or pharmacological therapy, is then usually helpful in decreasing intensity of symptoms and hastening more lasting recovery. Electroshock therapy appears to be most effective if begun when the disorder appears to have reached its peak intensity. Conversely, the provocation of an organic mental syndrome by electroshock therapy may mask improvement in the aged, and their disorganization of

thought and behavior may be mistaken for agitation, manic behavior, or psychomotor retardation.

Paranoid trends in the presence of depressive affect or manic behavior were in the past considered ominous and predictive of a long permanent illness. It is true that paranoid conditions in which little affect is displayed usually have a relatively poor prognosis. However, current personal, pharmacological, and physical treatments have improved the outlook for paranoid conditions. This may be attributed in part to the helpfulness of phenothiazines in decreasing anxiety and clarifying thought in such patients and also to the beneficial use of group meetings in which they are tactfully helped to be less fearful and more friendly.

Prevention

The incidence and prevalence of mental disorder in old age are high. With advancing age, there is increasing likelihood of losses in familial, financial, physical, and mental resources. The prevention of medical crises and meticulous attention to supportive regimens are prophylactic against disabling mental diseases of the aged. Thus, comprehensive medical care for this age group is of prime importance.

Families, community agencies, hospitals, clinics, and private physicians play important roles in providing for the many medical and psychiatric needs of the aged ill. Few families can provide, unassisted, the comprehensive care an aged ill person needs; consequently, he is usually undertreated at home. Families may ask for assistance later than is desirable for their good or the patient's welfare. Psychiatrists, physicians, and welfare agencies may mistakenly minimize the burden that the geriatric patient places on his family; worse, they may resist the admission of aged patients to their services and generate guilt by implying that families who appeal to them for aid want to avoid responsibility for their aged relatives' care. Many professionals share a popular misconception that families are eager to dump their aged kin; in actuality, the sick aged often have no families or have families who are themselves aged, ill, or struggling for survival, so that assistance must be provided by way of social organization. Basic services, the provision of adequate board and lodging, good general medical care, intelligently pursued efforts toward encouraging interest and activity, and psychiatrically supervised pharmacotherapy are unquestionably helpful in decreasing the intensity of long term reactions and in preventing the emergence of new depressive episodes.

Prevention of mental disorders in the aged is not yet possible, but the severity of prevalent disorders may be ameliorated and their incidence decreased. Vulnerability to affective disorder or brain damage leading to brain syndrome appears to be genetically determined in many persons. Nevertheless, the importance of inherited constitutional type and of incidental illness is suggested by the frequent association of arterial hypertension, atherosclerosis, arteriosclerotic car-

diovascular renal disease, diabetes, glaucoma, hyperthyroidism, and exaggerated adrenal cortical function with affective disorders. Not only do these conditions appear to evoke depressive reactions over and beyond the depressing effect of severe or long term illness, but persons in whom these conditions develop appear to be especially prone to mood-cyclic or depressive reactions and may have displayed this propensity even before appearance of the somatic disorder. Other conditions, such as peptic ulcers or asthma, are also seen in close association with depressive reactions, sometimes accompanying the disorder and at other times masking it and appearing to be depressive equivalents.

Laudable measures likely to help avert mental illness in old age for even the constitutionally susceptible include environmental advantages in early life conducive to optimal growth, development, education, choice of occupation, and economic security; minimal exposure to noxious substances, trauma, and disease; and maximal timely use of prophylactic and remedial medical services.

Anticipation of failure and actual failures that accompany decline of functional capacity and the loss of resources can lead to rational rather than irrational pleas and search for aid. Willingness to seek and accept socially organized and governmentally supervised assistance requires as a necessary complement the ready availability of protective, supportive, and rehabilitative services.

Ideally, the individual should be so well integrated that socioeconomic reverses, changed personal relationships, and stressful experiences would be handled without serious decrease in self-esteem, loss of self-confidence, or the emergence of serious doubts as to his purpose and sense of identity; he should feel challenged rather than defeated by adversity and should retain his desire to act and to do, within the limits of his capacity, despite loss of vigor and functional capacity. He should wish to maintain pleasurable personal relationships yet be able to tolerate the absence of congenial, companionable persons and not become desolate when he loses family members and friends. The sense of worth, dignity, and self-confidence should be preserved by social institutions and by the behavior of surrounding persons, which encourage feelings of personal control, of influence on others, and the belief that one has the capacity to contribute personally to the mastering of daily problems. Such social influences appear to favor the development of persons capable of social integration in old age who are also capable of tolerating isolation. However, most persons in our society do not achieve this ideal.

Although aging persons may fear death as an ultimate helplessness, they appear to be more afraid of humiliation, pain, mental suffering, and the loss of those for whom they feel affection or need. Most of all, they fear the loss of control over their own behavior or destiny. Consequently, in the very old and impaired, small victories that appear to win them a

place in the sun, protective attentions from a child, or the self-attained relief from tensions, as from bowel distress, may yield pleasures such as might be expected from a guarantee of everlasting fame. The belief that their will or wishes will be followed after death may elicit more joy than that which in the past might have followed on the attainment of riches. Because pleasure appears to accrue from a sense of effectiveness in personal action, whatever contributes to the aged person's belief that he is effective and efficient, as measured according to his own values, helps to preserve his emotional equilibrium and his psychological aplomb. It appears that the adaptive organism maintains its social poise, even in the face of obvious decline, when it feels its change is governed by choice; he who feels in command may die with little pain and small grief—even with joy.

Psychiatrists who can contribute to the understanding of aged persons are needed to consult, supervise, and teach in old age homes, nursing homes, general hospitals, state hospitals, old age centers and clubs, as well as to see and treat patients and their families in their offices, the homes of patients, and hospitals and clinics. They can exercise an important function by sustaining the morale of those who are concerned with the day-to-day care of the aged.

Suggested Cross References

Further information regarding specific psychiatric disorders may be found in the sections and chapters devoted to schizophrenia (Chapter 15), manic-depressive psychosis (Section 17.1), involutional depressive reaction (Section 17.3), paranoid reaction (Chapter 16), the organic brain disorders (Chapters 18 to 21), alcoholism (Section 27.3), suicide (Section 33.1), the neurotic disorders (Chapters 23 and 24), psychosomatic disorders (Chapters 29 and 30), and the borderline states (Section 14.2)—all in Area F, on the psychiatric syndromes. More detailed information regarding the various treatment modalities mentioned in this chapter is presented in Area G, on psychiatric treatment. Preventive measures in psychiatry are discussed in Area I, on community and social psychiatry, and fundamental concepts concerning social and cultural determinants of behavior are presented in Sections 4.2 and 4.1, respectively.

Chapter 48

Forensic Psychiatry

48.1 • • •

LAWRENCE ZELIC FREEDMAN, M.D.

Introduction

At various stages in their historical development, psychiatry and law have converged. There are further similarities in the problems with which they are now faced. Neither discipline can therefore be understood without some knowledge of the development and orientations of the other, for their influence is reciprocal and complementary. Both psychiatry and law are concerned with the social deviant, the person who has violated the "rules" of society and whose behavior presents a problem, not only because his deviance diminishes his ability to function effectively, but because it affects the functioning of the community adversely. Traditionally, the psychiatrist's efforts are directed toward elucidation of the causes and, through prevention and treatment, reduction of the self-destructive elements of harmful behavior. The lawyer, as the agent of society, is concerned with the fact that the social deviant represents a potential threat to the safety and security of other people in his environment. Both psychiatry and law seek to implement their respective goals through the application of pragmatic techniques, based on empirical observations.

History. A comprehensive account of the history of psychiatry has been presented elsewhere in this volume. However, many of the unresolved conflicts between psychiatry and law are legacies of their common background. A brief summary of those historical events which relate specifically to the evolution of psychiatry in its relationship to law provides an appropriate framework for this discussion.

Among the first acknowledgements of the relationship between psychiatry and law were the sacred writings of the Jews. These instructed the priest on the treatment of the mad and the sinful, as well as the sick. When Christ adjured his followers to cast out the devils within them, his words were directed to the mad and to those who were "evil," no less than the

lame and the blind. The first monasteries typically sheltered the physically ill, the psychically and spiritually possessed, the insane, and the impoverished under the same roof. This failure to differentiate between the various types of social misfits has persisted up to the present. Identical facilities for the bad and the mad may still be seen in psychiatric state hospitals and prisons throughout this country. One of the first attempts by a physician to influence legal process was the effort of Johannes Weyer, in the 16th century, to bring the persecution of "witches" to a halt, clinically observing that this peculiar behavior reflected the natural processes of disease, rather than supernatural intervention by devilish forces. But diabolism dies hard. A century later, Weyer's clinical demonstrations were declared legally invalid, on the grounds that he was a physician, rather than a lawyer.

Italy. During the Age of Enlightenment, the leaders of the Renaissance concerned themselves with the mentally ill and the criminally deviant. The experiments of Italian humanists with rehabilitative penology preceded the establishment of the famous Quaker penitentiary in Philadelphia by almost a century. Lombroso's classic studies of criminals were anthropometrically precise and rich in clinical detail. He reported that criminals shared specific traits such as impulsiveness, relative moral insensitivity to harm done to others, and distorted social values. His anthropometric methods resembled phrenology. Lombroso seemed to have proven that criminals could be distinguished from noncriminals by specific physical characteristics of their face and head as well as their criminal acts and personality. He believed that the criminals he studied had not progressed beyond an early stage in human evolution or had regressed genetically to a more primitive state. He, like many others of his scientific generation, was influenced by Darwinian theory. These anatomical speculations have since been rejected on statistical grounds; but psychiatric investigators continue to correlate physical characteristics with antisocial behavior. The issue is not yet entirely resolved.

Ferri, a contemporary of Lombroso, argued that the primary goal of the law was to abolish the social ills which give rise to crime, rather than to assign blame

for specific criminal acts or to affix moral guilt. The careers of juvenile offenders, he maintained, as have so many others since, provided no empirical justification for the belief that punitive methods, detection, conviction, and detention, could prevent later adult criminal behavior. Such punitive methods could not reduce the social cost of delinquency, for they contributed nothing to the rehabilitation of the delinquent. They failed to enable him to fulfill his constructive potentialities and live a more useful life. Ferri held that in a rational society basic satisfactions would be ensured to the youngster. Through such fundamental gratification, rather than punishment, the likelihood of repeated delinquency would be kept at a minimal level. Once a child or man has been convicted of an offense, society should act to rehabilitate, to restore him to the company of law-observant citizens before an irreversible recidivism has become fixed. His theory begins with the axiom that kindly social responses are more effective in the prevention of criminal behavior than harsh retaliation. Understanding and compassion would, if tried, prove more effective than punitive measures even in dealing with chronic criminals. Law enforcement officers have begun to acknowledge the validity of Ferri's arguments only very recently. With rare exceptions, the punishments for criminal behavior have been unrelievedly unimaginative and inadequate.

From Italy, too, came the first efforts to reform court procedure. Previously, the presiding judge had borne the responsibility for differentiating between truth and falsehood in the evidence presented. His decisions had been based primarily on his intuition. Judicial procedural reforms ensured a more objective, and hence more reliable and valid, assessment of the evidence.

France. The emancipation of the peasants by the French Revolution was followed by Citizen Pinel's efforts to free the inmates of Bicêtre from their chains. This event has been described as the first step toward the goal of voluntary hospitalization for the psychiatrically disabled, a goal which is still unrealized.

Pinel and his successor Esquirol played a major role in initiating other reforms in the treatment of the mentally ill. They maintained scrupulous and comprehensive clinical records, providing systematic description of various psychiatric disabilities, and assayed classifications of specific clinical syndromes. Through the years, psychiatric nosology has had a significant effect on the judicial response to the plea that criminal behavior be excused or its consequences minimized on grounds of irresponsibility due to mental illness. Esquirol's description of "monomania" as a mental disorder in which the patient's preoccupation with a single idea was associated with a tendency to discharge irrepressible impulses has played a very important legal role. The tendency to act on one's impulses may take the form of kleptomania, the repetitive compulsion to steal. Esquirol also described the clinical entity of *manie sans délire* (mania without delirium). The

psychiatric and sociological descendants of this psychiatric syndrome, which are variously described as the "neurotic character," the "sociopathic personality," and the "psychopathic personality," have become increasingly prominent as focal areas of concern for forensic psychiatry.

The pioneer investigations of hypnotism undertaken in France served to point up other possible areas in which the concerns of psychiatry and law may converge. Hypnotism became a legitimate therapeutic procedure only after it had been used for this purpose by men with medical training and stature, Charcot, Liébault, and Bernheim. Previously, the original dramatic demonstrations of "animal magnetism" by Mesmer had been discounted and ridiculed, first in Vienna, later in Paris where he fled. The checkered history of hypnotism exemplifies the dilemma, not yet resolved, of how effective legal controls can be imposed on charlatanism without penalizing or inhibiting legitimate scientific investigation, however unorthodox.

The practice of hypnotism also evoked the question of defining professional competence. It anticipated the contemporary debate as to whether a medical degree should be a prerequisite for the practice of psychotherapy in cases which do not require physical intervention. The potential value of contributions derived from nonmedical disciplines and the consequent importance of interdisciplinary collaboration would seem to be self-evident. In France, early in its development, criminology was recognized as the province of sociology, which Comte had established as the "queen discipline." Durkheim's classic contributions to our understanding of suicide and his construct of anomie have their roots in sociological theory. They parallel, to a remarkable degree, those clinical models of Freud which are of special interest to psychiatry and law.

England. Tuke's attempts to foster more humane treatment of the mentally ill have been described in the literature, as have the deplorable conditions at institutions, such as the Bethlehem Hospital, which inspired such efforts. Less emphasis has been placed on the fact that Bethlehem housed criminals as well as psychotics. These conditions were considered similar in that they aroused public anxiety. There is no indication of awareness of the possible role of psychiatric illness as a precipitating factor in criminal behavior until 1835, when Prichard, influenced by Esquirol's concept of *manie sans délire*, described the psychopathic personality as an amoral man who behaved impulsively and sometimes criminally to satisfy his immediate, overwhelming desire. He described the psychopathic personality as a person who had failed to learn from experience; who could not postpone immediate gratification of his desires, even when he was assured that his ability to endure such frustration for only a short time might produce greater but later rewards; and who, in order to fulfill his immediate needs, was willing to take risks and expose himself to

dangers which far exceeded the impulsive gratifications he might attain. The degree to which the psychopathic or sociopathic personality can be considered legally responsible for his criminal behavior has remained a crucial area of disagreement between jurists and psychiatrists.

Maudsley postulated that the mind was the instrument of the brain. Therefore a deranged mind was symptomatic of a diseased brain. He conceded that it was impossible to detect the presence of any anatomical defect by the techniques which were then available. Today, a hundred years later, we are still unable to validate hypotheses concerning the neurophysiological basis of the criminal behavior of the mentally ill.

German-speaking countries. In Germany and the German-speaking countries, an intimate and important relationship existed between psychiatry and law, especially in the 19th century. Krafft-Ebing described the clinical symptoms of sexual aberrations with encyclopedic thoroughness. Wagner-Jauregg's malaria treatment and Ehrlich's salvarsan injections began the assault on general paresis, then a major medico-legal problem. Kraepelin's classification of the varieties of mental disease was so comprehensive that it had unexpected and possibly undesirable consequences. The severe psychiatric syndromes, which he called dementia praecox and manic-depressive psychoses, became equated with legal irresponsibility. Bleuler refined Kraepelin's concept of dementia praecox to include the various schizophrenias. These diagnoses, too, have frequently, but incorrectly, been accepted as the equivalent of legal insanity. Forel, the superintendent of the great Swiss mental hospital, Burghölzli, led the fight against alcoholism and other social and legal ills. He relied primarily on moral suasion. Most recently, Piaget conducted important investigations of the development of a moral sense in the child. In Austria, Freud's investigations of the unconscious led him to delineate the psychiatric defense mechanisms in the developing child and to assess their influence on the character structure of the adult. He proposed a tripartite model of personality, comprising an instinctual id, a reality-testing ego, and a self-judging superego. On the basis of his intensive clinical studies, Freud hypothesized that in some cases the sense of guilt preceded rather than followed the commission of a crime. For such men, the prospect of punishment predisposed rather than deterred the illegal behavior. This theory added a fourth dimension, the need for punishment, to the three traditional legal rationales for punishment, the triumvirate of deterrence, retaliation, and rehabilitation.

Subsequently, Aichhorn applied psychoanalytic principles to "wayward boys." The mode of punishment in each case was determined by the boy's psychological needs.

Alexander, a psychoanalyst, and Staub, a jurist, wrote the first text in which legal and psychoanalytic insights were applied to the criminal. Persons whose il-

legal acts were in harmony with the distorted values of their environment and their ego structure were described as "normal criminals." Those whose crimes sprang from deeply repressed conflicts of which they themselves were unaware were labeled "alloplastic characters." There is a crucial difference between the autoplasic psychoneurotic commonly encountered in clinical practice and the alloplastic character. The psychoneurotic suffers from the symptoms of his conflict. The alloplastic personality "acts out" his conflicts. When he violates the rules of society in the process, he may become a criminal.

The United States. Of particular significance for forensic psychiatry was the publication in 1832 by Dr. Isaac Ray, a young general practitioner in Eastport, Maine, of a remarkable volume, entitled *Insanity and Jurisprudence*. Dr. Ray's work is probably the most important single contribution to medical jurisprudence published in English. A decade later it was cited in the crucial McNaughten case, which has influenced the concept of legal responsibility in this country and Great Britain up to the present.

The Psychiatrist and the Law

Psychiatric practice: Legal requirements. The license to practice medicine and surgery which is required in every state throughout the United States carries with it legal authorization to engage in the practice of psychiatry without prior specialized training. Consequently, the impetus to acquire further training, which in fact is a prerequisite for competence in this field, must stem primarily from the physician's sense of professional ethics. Moreover, in contrast to every other medical specialty, in most states persons without medical training, indeed persons who have had no formal training whatsoever, may practice psychotherapy. In a few states, laws have recently been enacted which make training and certification mandatory for clinical psychologists. For the most part, however, the psychiatrist engaged in the practice of psychotherapy is carrying out a treatment for which no formal training or licensing is required by law.

Confidentiality and privileged communication. Medical ethics, as well as therapeutic considerations, demand that the psychiatrist hold anything his patient may tell him in strict confidence. In other words, confidentiality is an ethical imperative for the psychiatrist. Privileged communication refers to the patient's legal right to refuse to divulge the nature of his transactions with his psychiatrist during therapeutic sessions. The claim of privileged communication is an accepted tradition in client-lawyer relationships, but it is rarely granted for patient-psychiatrist confidences. In recent years, a few states have enacted statutes providing for privileged communication in psychiatric treatment.

The clinical interview and the accused. The psychiatrist has no formal role in criminal investigation.

He is under no legal or ethical obligation to use his skills to elicit confessions from criminal suspects. To do so is usually inconsistent with his professional code of ethics. If he were to reveal information obtained in a clinical setting, the psychiatrist would rob the psychiatric interview of its essential ingredient: confidentiality.

Two devices of psychiatric interest used to elicit confessions from those suspected of crime are popularly referred to as the "lie detector" and "truth serum." The first, a polygraphic instrument, is designed to measure changes in cardiac rate and output, respiratory rate, skin perspiration, and other physiological responses which are significantly affected by the autonomic nervous system. Deviations from the subject's mean according to these parameters, in response to verbal cues betraying "guilty knowledge," are regarded as putative evidence of his guilt or indications of his knowledge of the crime. "Truth serum" is usually some form of sedative, most often a barbiturate, which lowers the suspect's conscious self-censoring defenses and is presumed to predispose him to disclosing the "truth."

The polygraph has been employed more widely than the drug, not only in police investigations but for government security clearance and screening for industrial pilferage. It is true that autonomic hyperactivity can be detected by polygraphs; and it is true that deep sedation may lower protective barriers against self-disclosure. Neither technique is infallible. Muscular hypotonus, hypertonus, malingering, and psychic states of which the subject may be unaware can affect autonomic excitability. Moreover, lowered cognitive thresholds may release private fantasy as well as "truth." The psychiatrist's use of drugs, hypnosis, or the potent ancillaries of the clinical interview (transference, empathy, dependence, and suggestion) to elicit confessions, if they are to be used ultimately to bring about legal sanctions, is undesirable.

The psychiatrist as expert. Any psychiatrist may become involved in legal proceedings as an expert, a medical specialist on mental disorders. His participation might arise from the request of a defendant whose competence to handle his own affairs, to enter into contracts or to execute legal documents has been challenged. The psychiatrist sometimes acts at the request of one or more persons who have made such claims against the defendant. He also participates in court proceedings in response to the invitation of an appropriate agent of government, usually the presiding judge. As a medical specialist on medical disorders, the psychiatrist may serve federal, state, or local government as a medical officer or staff member of an administrative or institutional unit.

Psychiatrists retained as experts for the defense in a criminal trial may declare a man "insane" and "not responsible," while opposing experts testify on behalf of the prosecution with equal conviction that the defendant was "sane" and "responsible." In a contest over a will, a psychiatrist testifying for one group of

relatives may assert that the man who had made the will was "incompetent" to do so. Almost invariably, however, the beneficiaries of the will are able to produce another, equally prominent expert, who insists that the deceased was entirely "competent" to dispose of his property by writing and signing a legally binding will. There are six possible explanations for such disparities: (1) Honest differences of opinion are inevitable in any effort to formulate complex judgments. (2) Our knowledge of the human personality in its normal and abnormal manifestations is imperfect, at best. (3) The fact that complex problems must be resolved with imperfect tools and incomplete knowledge tends to enhance the unconscious bias and partisanship which are likely to arise. (4) Frequently, medical experts are not fully conversant with the language, practices, and objectives of the legal procedure in which they are participating. (5) There is a common misapprehension among medical experts that in offering testimony they must use legal language as their own. (6) Finally, although this occurs only very infrequently, occasionally the venality of a medical expert may induce him to present testimony which is favorable to the individual or group which has retained him.

Honest differences of opinion may be minimized, but they can never be eliminated entirely. Research in the behavioral sciences is on the threshold of a major breakthrough which, within the next generation or two, will certainly bring our understanding of psychopathology up to a level comparable to that achieved by most other medical specialists within the last several generations. With regard to the possibility that unconscious bias and partnership may influence the expert's testimony, since, for the most part, this occurs when the data available to him are ambiguous, it follows that the lessened ignorance and confusion which can be expected as a result of scientific advance will be accompanied by a concomitant decrease in bias.

There is no need to perpetuate the most common cause of the frequently conflicting, sometimes chaotic, testimony of the psychiatrist during legal proceedings, which results primarily from the fact that he does not fully understand his role and function in the courtroom. When his actions and testimony are appropriate to the medical specialist who, by virtue of his training and experience, is an acknowledged expert in the field of mental and emotional disorder, much of this confusion is eliminated. The psychiatrist's task is to present such facts and opinions as lie within his professional competence. His language should be clear, and he should avoid technical terms whenever possible. When the use of specialized terms is essential, he should define them with as much lucidity as his verbal facility and the circumstances permit. When giving testimony, his answers should be relevant and succinct. The psychiatrist must remember that he is neither a legal agent nor a legal expert. The responsibility for the resolution of questions of law belongs to the judge, the jury, and the contending attorneys. The psychiatrist can present

pertinent facts which fall within his professional knowledge and offer his opinion as to their significance. However, he is an expert and not a judge and jury. The legal decision makers will ultimately base their judgment on the testimony, impressions, and reports of other experts and witnesses as well as his.

Problems of communication. The interpretation of legal language and psychiatric language may differ radically, even when the same words are used in both instances. Some classic examples of problems which typically arise in communication between these disciplines and represent a major source of misunderstanding are cited below.

Commitment. In psychiatry and law alike, by definition, commitment of the psychiatric patient refers to one of several legally implemented, psychiatrically inspired procedures designed to permit involuntary hospitalization of certain categories of the patient population. In fact, however, for the lawyer, a commitment is a *mittimus*, a warrant for imprisonment. On the other hand, for the psychiatrist, the term denotes a "helpful" procedure, in that it facilitates the hospitalization and appropriate treatment of a patient who is mentally ill. The difficulty may be attributed, perhaps, to the fact that the word has historic, and still viable, punitive associations, in contrast to its therapeutic significance for psychiatrists. But, whatever the explanation, it has been the source of frequent misunderstandings.

Insanity. Although the word "insanity" is no longer used in more recent legislation and judicial decisions, it appears in the legal decisions and legislation which were based on the concepts of the alienists of the 19th century. It was then used as a generic term, which referred to a group of severe mental disorders which persisted over a relatively long period of time. In contemporary psychiatry, the term has been abandoned; nevertheless, it remains a legal legacy. It connotes a degree of mental disturbance so severe, menacing, or disabling that the law may rule the patient immune from certain legal responsibilities or disallow certain privileges which require a degree of competence, such as the power to marry or to enter into business contracts. In some states, "insanity" is the relevant criterion for compulsory hospitalization. Thus, what was once an anachronism in psychiatry is fast becoming one in the law.

The legal interpretation of the word "insanity" presents a problem in communication primarily because it has never been clearly defined, although it is generally recognized that insanity is not the equivalent of psychosis. Professor Henry Weihofen's comments are particularly appropriate in this connection:

For a branch of learning which consists largely of definition, the law is strangely lax in the use of the word 'insanity.' Unfortunately, the word has no technical meaning either in law or in medicine, and it is used by courts and legislators indiscriminately to convey either of two meanings: (1) any type or degree of mental defect or disease, or (2) such a degree of

mental defect or disease as to entail legal consequences (i.e., as to require commitment to a mental institution, or the appointment of a guardian, or to avoid a contract or relieve from responsibility for crime).

Mental competence. The legal connotation of the phrase "mental competence" is easily confused with, but not identical to, its current psychiatric interpretation. In the legal sense, mental competence refers to a degree of mental soundness consistent with the ability to carry out certain civil acts of a juridical nature, e.g., writing a will or signing a contract. When it is applied to the criminal, it refers to whether he demonstrates a degree of mental soundness compatible with standing trial. If he is competent, then he must also be proven responsible for the illegal act of which he stands accused.

Laws governing hospitalization. It is preferable to have a patient enter a mental hospital or the psychiatric in-patient service of a general hospital voluntarily, for the same reasons that his prognosis is better if he enters psychotherapy as an out-patient through his own decision, because he wants to help himself. Some states specifically forbid commitment to a general hospital. The official policy in many such hospitals is to accept only voluntary patients. Most city, county, and state hospitals in this country recognize legal commitment procedures. The experience of government hospitals in such countries as Holland and England, where voluntary admissions are the rule, indicates that such legal formalities are neither necessary nor desirable. Moreover, it is the current consensus of opinion that involuntary commitment is and should be a minor problem, involving a very small fraction of the psychiatric patient population. Certainly it should not continue to dominate our practice.

All of the states provide for some form of involuntary hospitalization. Such action is usually taken when the psychiatric patient presents a danger to himself and to others in his environment, to the degree that his urgent need for treatment in a closed institution is evident.

Hospital admission procedures

Voluntary admission. The procedure followed in the voluntary hospital admission of psychiatric patients does not differ significantly from the admission of patients for other forms of medical treatment. The patient, who is usually referred to the hospital by his private physician, simply indicates his desire to be admitted. Following psychiatric examination by a member of the staff, he enters to remain as long as he wishes or the doctors consider necessary.

A similar procedure is followed in cases of voluntary commitment with one exception: the patient must sign a written statement in which he agrees to remain in the hospital for a specified minimum period of time. However, the importance of this agreement lies in its psychological, rather than its legal, significance.

Involuntary hospitalization. The various categories

of involuntary hospitalizations may be graded on a continuum, beginning with emergency or observational admissions. These admissions usually require the certification of two physicians who are not associated with the hospital to which the patient is sent. In such cases, the period of hospitalization is relatively brief in duration, ranging from 48 hours to 1 month. Involuntary long term hospitalization, which is commonly referred to as probate commitment, involves some form of court procedure and judicial decision. The differences between emergency or observational commitment and probate commitment are more apparent than real. While the psychiatric patient may be hospitalized for a very brief period without legal sanction, all involuntary hospital admissions are subject to judicial control. Judicial action is based on the clinical reports of reputable physicians and psychiatrists.

An emergency admission implies the sudden onset of acute psychiatric disturbance. Not surprisingly, hospitalization under such circumstances does not require the consent of the patient; emergency commitment can rarely be invoked without the cooperation of the family. This form of hospitalization is limited in duration, and it is equally limited in terms of therapeutic effectiveness. Its social value lies in the fact that the patient, who is considered to represent a source of danger to himself and others, is removed from his environment and confined to a psychiatric facility for a specified period of time. During this period, diagnostic studies can be undertaken to determine the extent and nature of the patient's disorder and, on the basis of such considerations, whether he should be hospitalized for a longer period of time, in which event legal action must be taken in probate court.

Hospital records. Once he has been admitted to the hospital, the success of treatment will depend in part on the degree to which the patient's dignity is respected by the staff, as evidenced, in turn, by their efforts to keep the details of his treatment confidential. It should be emphasized that, even when the patient is admitted to the medical or surgical service of the general hospital initially and referred for psychiatric treatment later, the voluminous psychiatric case record, with its detailed account of the patient's intimate fantasies and hidden feelings need not become part of his general medical record. This can remain part of the psychiatric unit's own record system, which is inaccessible to other staff members. Instead, the psychiatrist should prepare a précis of the patient's current mental status. The data contained therein can serve as a guide which will determine the quality of the physician's relationship with the patient and alert him to the signs of recurrent psychiatric crises.

Reports should be sent to outside agencies only when they serve the therapeutic needs of the patient and, in that event, should contain only those data which are essential for the agency's effective functioning on his behalf. When information which was obtained by

promising the patient confidentiality is requested for purposes which may be inimical to his interests, both the psychiatrist and the hospital are under a moral obligation to maintain that pledge. Psychiatric records must be made available if they are subpoenaed for legal purposes. However, even under these circumstances, the records usually remain in the custody of a representative of the hospital.

Hospital discharge. In most states no special provision is made for the commitment of psychiatric patients to general hospitals. The law specifically prohibits any attempt to restrain those patients who wish to leave the hospital. A voluntary patient in either a private or a public hospital may leave whenever he wishes, with or without the approval of the staff. When his action does not meet with the approval of the staff, the patient or a member of his family is requested to sign a statement to the effect that the patient is leaving the hospital against professional advice. In fact, the patient is not required by law to sign such a statement. Psychiatrists as well as patients seem to share the misconception that it is obligatory; it has considerable suggestive power and may prove an effective deterrent to discharge. In rare instances where the patient is considered to represent a serious potential danger to the environment, the hospital, usually in cooperation with the family, may obtain a probate court order to hold the patient for further treatment.

The situation is more complex with regard to involuntary hospitalization. The underlying legal philosophy remains the same: any person in this country who is restrained against his will, for whatever reason, may seek his release through the ancient Anglo-Saxon petition of habeas corpus. A psychiatric patient or responsible persons acting in his behalf may, through the writ of habeas corpus, require the superintendent of the hospital to which he has been sent against his will to appear before a judge. The superintendent is obliged to demonstrate to the judge's satisfaction that the patient has been deprived of his freedom for just and lawful cause. If the superintendent is unable to provide adequate evidence to justify the involuntary hospitalization of the patient, the court may order his immediate discharge.

Barton has formulated what might be called a patient's Bill of Rights. Any person has the right to seek hospital admission for psychiatric care without public humiliation; and his freedom shall be restored when such care is no longer required. During the period of hospitalization, he shall have the right to communicate and the right to protection and privacy. He shall be considered competent to conduct his own affairs and to exercise his rights as a citizen unless he has been proven incompetent, and the preservation of his civil rights shall be assured.

Malpractice. The psychiatrist may be sued or even criminally prosecuted if his patient suffers unnecessarily as a result of his incompetence or negligence

The number of malpractice suits in psychiatry, as in medicine in general, has increased somewhat in recent years. As a general rule, however, the psychiatrist is protected from civil or criminal sanctions if he exercises a level of competence and caution consistent with that of other medical practitioners. No procedure which involves a physical or mental risk should be undertaken without the patient's prior written consent, and the patient should know what he is signing. No somatic treatment should be undertaken without the express consent of the patient, or, if the patient is seriously incapacitated, of his guardian or a responsible member of the family. When such minimal precautions are taken, the threat of legal action, while sufficiently realistic to warrant malpractice insurance, is not a matter for serious concern.

The Psychiatric Patient and the Law

Psychiatrists point out that legal disputes frequently have their roots in psychiatric problems, however rational such conflicts may appear once they have been translated into the language of our legal system. Psychiatrists have further suggested that the rituals of law may themselves give symbolic expression to unconscious desires, fears, and impulses which are quite far afield from the ideal of rational jurisprudence. However, they frequently fail to realize the degree to which the guilt-apportioning and punishing operations of the law affect the guilt feelings and self-punishing tendencies of our patients. Certainly, it is not rare for a psychiatrist to hear manifestly "socially impeccable" patients describe illegal acquisitions, aggressions, and sexual adventures which are condemned by society or even legally prohibited. Although such activities are actually carried out only infrequently, every psychiatric patient has talked about his thoughts, or fantasies, or desires to carry out illegal sexual or aggressive acts at some point in his treatment.

A sense of guilt without legal cause is probably encountered more frequently among psychiatric patients than it is among legal clients, in whom, by virtue of their criminal behavior, there is ample justification for such guilt feelings. One of the basic shibboleths of democracy is that whatever the individual may think privately, he is not considered to have committed a crime unless he acts on his thoughts. The determination of legal guilt depends on proof of the *actus reus*, illegal act, as well as the *mens rea*, illegal intention.

The clinician cannot fail to be impressed by the formidable number of illegal acts which are committed by middle and upper class patients, and remain undetected. Under similar circumstances, the lower class patient is less likely to remain unapprehended. Psychiatric treatment may be a consequence of his illegal act. It is reasonable to assume that the psychiatric patient from an economically depressed area, or a socially or ethnically disadvantaged group, has been

referred for treatment by an official law enforcement agency, the courts or the prisons.

A study of the neurotic patient population in a medium-sized New England city showed that 20 per cent of the subjects investigated were in treatment as a direct consequence of their legal difficulties. In patients at the lowest socioeconomic level, in 42 per cent of the cases studied, psychopathology had manifested itself initially in the patient's provocative interaction with the community, for which he had been arrested, tried, and convicted.

With respect to the middle and upper middle class patients in the population studied, findings supported hypotheses previously advanced in this connection: criminal fantasies and impulses occurred with at least equal frequency among patients in these socioeconomic categories. Typically, however, their psychopathology found overt expression in feelings of subjective discomfort and general malaise, rather than difficulties in social adaptation. (When difficulties in social adaptation had occurred, they had not come to the attention of the authorities.) Nevertheless, over the long term, the often unconscious antisocial tendencies of this group of "socially favored" patients, which included the power elite, represented a greater potential danger to the community than the more capricious conduct of the lower class patients.

The criminal patient population. Psychiatrists concerned with offenders may treat sexual and aggressive deviates. These clinical entities continue to present a major psychiatric and social challenge. Since sexuality and aggression play a crucial role in personality development, the psychiatrist's efforts on behalf of this segment of the patient population are of obvious significance. Those individuals whose criminal behavior involves the illegal acquisition of goods, i.e., run-of-the-mill thieves, are rarely encountered in psychiatric practice. It is true, of course, that occasionally compulsive embezzlers or shoplifters come for therapy, and useful clinical generalizations may be drawn from their treatment. However, these cases are not representative of the mass of acquisitive offenses which account for the major share of socially and legally disruptive behavior in our society.

The "profile" of the adult criminal. Epithets such as "murderer," "thief," and "pervert" express the feelings of revulsion and acute anxiety which typify the reactions of the average law-abiding citizens to persons who frighten, anger, annoy, or disgust them. Concomitantly, their evaluation of the personality of an offender will depend primarily on the nature of his "crime," even though this offense may represent a single isolated event in a lifetime. Certain types of criminal behavior evoke a particularly intense reaction among the general population. Yet the ubiquity of criminal impulses and fantasies, both aggressive and sexual, as revealed in psychiatric clinical practice as well as in sociological field studies, clearly demonstrates that

the criminal cannot be sharply distinguished from the general population. He is the crystallized expression of certain aspects of normal functioning, on the one hand, and personality disturbance, on the other. As such, he is as much the concern of psychiatry and the behavioral sciences as of the law.

Clinical experience has also shown that the criminal's personality structure is the product of a remarkably consistent intrapsychic organization, which permits reliable prediction of his characteristic behavior patterns. Thus, the criminal may manifest transient variations in emotion, behavior, ideation, and affect if there is some modification of the external milieu; but, unless a significant intrapsychic change occurs, the ultimate recurrence of his habitual behavioral patterns is inevitable. Nor is this surprising when one considers that a compulsion to repeat, which imperiously asserts itself, adjusting to environmental factors rather than being deterred by such variables, is characteristic of normal, as well as neurotic and psychotic functioning. Under the circumstances, it is reasonable to assume that repetition compulsion must play a crucial role in the etiology of provocative antisocial activity.

It has been established that convicted and imprisoned criminals usually come from disadvantaged socioeconomic groups. The percentage of minority groups members from deprived environments in our prison population far exceeds their proportion in our general population. Therefore, in addition to the consequences resulting from his conviction, the criminal suffers from a social vulnerability imposed by his environment. The ease with which these vulnerable criminals are repeatedly detected and imprisoned seems to indicate a self-imposed amenability to punishment. These data correlate with the characteristic and clinically significant variations which have emerged in studies of the intrafamilial, peer, and community relationships within this group.

Social patterns of illegal behavior. Alcoholism is a frequent concomitant of every form of delinquent behavior and is associated with crimes of violence. The "evils" of alcohol have long been a subject for dispute. On the one hand, "social drinking" is a prevalent practice in our society and, as such, is accepted and expected. On the other hand, the secret drinker represents a potential psychosocial hazard. Furthermore, when it is consumed in excess, alcohol may lead to serious somatic pathology. Alcoholism was the focus of one of the most significant political experiments in American history, the use of legal measures to resolve a psychosocial problem. The Twenty-First Amendment to the Constitution, which outlawed the manufacture, distribution and consumption of intoxicating beverages, is acknowledged today as a failure. People continued to drink (and to demonstrate their lack of respect for the law), and a huge illegal industry was formed to satisfy their demand for liquor. Some govern-

ment officials, as well as previously law-abiding citizens, were corrupted. Although the Twenty-First Amendment was repealed several decades ago, its influence persists in current social patterns of illegal behavior. Well organized groups of racketeers have permeated and gained control of other aspects of business, industry, and government. The fact that these individuals are permitted to continue their illegal activities can be attributed, in turn, to a secondary effect of the Twenty-First Amendment, the widespread suspicion of law enforcement agencies. Both of these patterns are legacies of Prohibition.

Irrational legal attitudes regarding alcoholism persist as a concomitant of delinquent behavior. Environmental factors play a major role in the etiology of the disease, and onset is precipitated by specific personality factors. The range of contributing causes is matched by a wide spectrum of treatment procedures, ranging from the chemical to the inspirational, which are described in further detail elsewhere in this volume. Yet the rate of chronic alcoholism continues to rise among the general population, and, while psychotherapy would seem to be indicated in many such cases, alcoholics are still sent to jail when they become obstreperous.

Narcotic addiction resembles chronic alcoholism in that it represents another troubling amalgam of undetermined somatic and psychic pathology, together with unresolved sociolegal issues. The widespread preoccupation with narcotic abuse was demonstrated at the White House Conference on Narcotic Addiction. The report prepared by the Ad Hoc Committee for the Conference participants emphasized several important points. First, narcotic abuse is decreasing; however, the intake of psychoactive but non-narcotic drugs, such as barbiturates and dexedrine, is increasing. The report further stated that the members of certain marginal subcultures seek, through the use of narcotics, to breach their alienation and to achieve the sense of social cohesiveness and euphoria which the dominant community pursues through the use of alcohol, still the most widely used addictive drug.

The report concluded that the narcotic addict can be cured; however, long imprisonment or indefinite ambulatory maintenance dosages were rejected as suitable therapeutic measures. Instead, the report recommended the view of the American Medical Association as well as the National Research Council of the National Academy of Sciences that the addict can be treated most effectively in an institutional setting, where drug consumption can be controlled. The medical professional is generally agreed that the view of addiction as a crime is irrational and self-defeating.

The psychological implications of imprisonment. The individual who is a recognized criminal, whatever the precipitating factors or the nature of his crime, will not necessarily be imprisoned. Imprisonment is, in itself, a special experience of such traumatic pro-

portions that the ex-prisoner is least likely to respond favorably to rehabilitative efforts.

The psychiatrist must be alerted to the special problems presented by this segment of the patient population. The prisoner lives in a tension-ridden totalitarian community. Dominated by other men, he becomes resentful and rebellious. Without women, he faces the challenge of an endemic homoerotic and homosexual environment. His isolation from and rejection by the community at large lowers his self-esteem, and he becomes reactively assertive. He is constantly preoccupied with fantasies of escape and the frustrations of his impulses toward self-expression. As might be expected, his attitudes toward prison personnel are highly ambivalent. The noninmate is feared, suspected, and rejected as a potential danger. As a representative of punitive society, he might inflict an injury on the prisoner. But for the prisoner the noninmate is his only possible ally in his unceasing quest for freedom.

The Concept of Legal Responsibility

Definition. The word "responsibility" is commonly used to denote trustworthiness and dependability. These subjective characteristics are not identical with legal responsibility, however. In law, responsibility signifies culpability, and hence punishability. According to criminal law, a socially harmful act does not represent the sole criterion of a crime. The objectionable act must have been perpetrated deliberately. The criminal must have had a *mens rea*, an evil intent. There cannot be a *mens rea* if the offender's mental status is so deficient, so abnormal, so diseased, as to have deprived him of the capacity for rational intent. The law can be invoked only when an illegal intent is implemented or attempted. Neither behavior, however harmful, nor the intent to do harm is, in itself, grounds for criminal action.

History. The precedent for determining legal responsibility was established in the British courts in 1834. A deluded young man, McNaughten, killed the secretary to the English Prime Minister, Sir Robert Peel, but was later acquitted by reason of insanity. After the trial, fifteen English judges were asked to answer five questions posed by the English House of Lords, in the hope that their answers might serve as a future guide in defining the limits of legal responsibility in similar cases. The responses to four of these five queries comprise the so-called McNaughten rule, which has, until recently, determined legal responsibility in England and in most of the states in this country.

The relevance of these questions and answers may best be understood if they are divided into two separate categories, namely, those relating to delusions and those concerning appropriate procedures and general criteria for determining responsibility. Concerning the effect of delusions, the exchange was as follows:

Question I: "What is the law respecting alleged crimes com-

mitted by persons afflicted with insane delusions in respect of one or more particular subject or subjects; as for instance where at the time of the commission of the alleged crime, the accused knew he was acting contrary to law, but did the act complained of with a view, under the influence of insane delusion, of redressing some supposed injury or grievance?"

Answer I: "Assuming that your Lordship's inquiries are confined to those persons who labor under partial delusion only, and are not in other respects insane, we are of the opinion that notwithstanding the party did the act under the influence of insane delusion, he is nevertheless punishable if he knew at the time of committing such crime that he was acting contrary to law; by which expression we understand your Lordship to mean the law of the land."

Question IV: "If a person under an insane delusion as to existing facts commits an offense in consequence thereof is he excused?"

Answer IV: "The answer of course must depend upon the nature of the delusion; but making the same assumption as before, namely, that he labors under such partial delusion only, and is not in other respects insane, he must be considered in the same situation as to responsibility as if the facts with which the delusion exists... were real."

The following dialogue has, since 1834, been the basis of our laws governing criminal responsibility:

Question II: "What are the proper questions to be submitted to the jury when a person alleged to be afflicted with insane delusions... is charged with the committing of the crime, and insanity is set up as a defense?"

Question III: "In what terms ought the questions to be left to the jury, as to the prisoners' state of mind at the time when the act was committed?"

Answers II and III: "...every man is presumed to be sane and to possess a sufficient degree of reason to be responsible for his crimes.... To establish a defense of insanity, it must be proved that at the time of committing the act the party accused was laboring under such a defective reason from disease of the mind, as not to know the nature and quality of the act he was doing, or if he did know it, that he did not know that he was doing what was wrong. The mode of putting the latter to the jury has generally been whether, at the time of the act he knew right from wrong, which mode is not as accurate when put generally and in the abstract as when put with reference to the party's knowledge with the respect to the very act with which he is charged. If the questions were to be put as to the knowledge of the accused solely with reference to the law of the land, it might confound the jury to believe that an actual knowledge of the law of the land was essential to lead to a conviction; whereas the law is administered on the principle that every man must be taken to conclusively know it, and the usual course is to leave the question to the jury whether the accused had a sufficient degree of reason to know he was doing an act that was wrong, accompanied with such observations and explanations as the circumstances of each case may require."

Thus, the answers to the questions stimulated by the McNaughten case define specific criteria which the court, judge, and jury could apply to exculpate a person accused of a crime by declaring him irresponsible. In summary, a man should be considered irresponsible, the Legal Lords said, if he was unaware of the nature and consequences of his act, or if he was incapable of realizing that his act was wrong. The Lords also declared that a delusion, to absolve a man from punishment, had to be one which, if true, would be an adequate defense. If the deluded idea did not justify the

crime, then presumably the man was to be held responsible, guilty, and punishable.

Current concepts. Alienists protested immediately and have ever since that these criteria are exclusively intellectual; that emphasis on intellectual capacity alone is misleading. They complained that they could not testify competently under such arbitrary legal restrictions. The lawyers replied that these were not medical standards of insanity but legal standards of responsibility. And so it has gone for over a century.

In 1869, New Hampshire adopted a rule of responsibility which placed psychopathology in the same category as physical pathology and other scientific and technical problems which required expert assessment and diagnosis. Psychiatric experts were to testify to the best of their ability, in accordance with their highest standards of professional competence, concerning the mental state of the person they had investigated clinically. Their data and opinions, like all information obtained from experts on technical questions, then became part of the complete summary of facts available to the judge or jury. The psychiatric expert's testimony, treated as one set of facts among many, was then to be evaluated by the judge or jury to ascertain its proper relationship to the legal requirements of *mens rea* and responsibility. This straightforward, sensible solution, however, remained a single oasis of rationality in northern New England. Until recently, the rest of this country and England have continued to comply with the tortured and confusing requirements of the McNaughten rule (although the sensible Scots added the concept of an intermediate state of partial responsibility to the rigid dichotomy of all or none decisions on responsibility or irresponsibility).

Courts in some states have added equally ambiguous criteria of the "irresistible impulse" to the ill defined criteria of knowledge and awareness stated in the McNaughten rule. According to it, an accused person may not be held responsible for his crime if, at the time, he was overwhelmed by impulses so sudden, imperative, and powerful that they were, in fact, irresistible. Not surprisingly, these irresistible impulses have been generally unprovable or at least unpersuasive in our courts. Judges and juries alike have been unable to distinguish between the unresisted impulse where the culprit, possessing "free will," had chosen not to resist, and the irresistible impulse where the defendant's "free will" was unequal to the task of restraining his impulse. This skepticism was most explicitly and succinctly expressed in the comment of an Ontario judge who suggested that a rope be dangled in front of a defendant claiming irresistible impulse to determine whether his impulses were, in fact, irresistible.

The social philosophy underlying this cynical attitude may be traced back to British tests for responsibility which predated the McNaughten rule and were still applied during the 19th century. Before Mc-

Naughten, the "policeman at the elbow" test was one important test of responsibility. The judge or jury tried to ascertain whether the defendant would have carried out the criminal act of which he was accused within sight of a policeman. Presumably, if the immediate prospect of detection, arrest, and punishment failed as a deterrent, then the man was legally irresponsible, for he was incapable of controlling himself. The loopholes in this test are obvious. Alienists of the 19th century and psychiatrists of the 20th century pointed out that even deteriorated patients in psychiatric institutions were often secretive concerning acts which they knew to be forbidden. Their argument that the dangerous paranoiac might be the most cunning of all in effecting harmful behavior so as to escape detection and punishment was equally ineffective.

In 1963, Oswald assassinated the President without witnesses; this secrecy does not, in itself, attest to his sanity. Nor is the fact that Jack Ruby shot Oswald in the midst of a host of policemen and before many millions of eye witnesses an adequate basis for psychiatric evaluation. This killing before a myriad of policing eyes was held to be the act of a legally responsible man although there was no evidence that dangling a rope before Ruby's eyes or the presence of a battalion of police "at his elbow" had any inhibiting effect. It is reasonable psychological conjecture that, for Ruby, public exposure may have contributed toward rather than mitigated against his tragic act. By his publicly rectifying a terrible wrong, he could openly display his courage and so could identify with the law enforcement officers whom he envied. Guiteau assassinated President Garfield in the presence of police but was found guilty and hanged in spite of psychiatric testimony which emphasized his emotional instability. Czolgosz killed President McKinley within inches of guards, and the assassin was whisked off to trial and execution before he could be adequately studied by alienists. The evidence indicated that he was a rootless, confused wanderer who was in all probability deeply disturbed emotionally, but nevertheless was able, perhaps encouraged, to commit homicide with many policemen at his elbow.

In 1954 the Federal Appellate Court in Washington, D.C., held, in the case of Monte Durham, that a man should not be held responsible for an otherwise criminal act when his behavior was the "product of mental disease or deficiency." This decision resembled the New Hampshire policy promulgated a century earlier. More recently, the American Law Institute included a formula for determining legal responsibility in its monumental Model Penal Code, prepared by leading American scholars and legal authorities over a 10-year period. The Code would free from responsibility anyone who, because of mental defect or deficiency, was incapable of appreciating the criminal nature of his act or, if he did appreciate its criminal nature, was nevertheless unable to control his behavior. However, the Code cautions that mere repetition of harmful

antisocial behavior would not, in itself, free a law-breaker from responsibility for his act. This point was explicitly stated to prevent the habitual criminal from escaping punishment.

Another Federal Appellate Court decision handed down in the Currens Case freed from responsibility those offenders who are unable to control their behavior. The ability to control one's behavior is the crucial criterion of legal culpability, rather than perceptual, intellectual, or emotional traits. The decision in the Gorshen case in California introduced into American jurisprudence a concept resembling in some respects the century-old Scot notion of partial responsibility. Mental disability might serve as a mitigating circumstance; therefore, it could determine the nature and duration of the punishment of the convicted criminal (whether penal incarceration or therapeutic treatment as an out-patient or in-patient), rather than simply the guilt or innocence of the accused. California also instituted two separate trials in criminal cases involving the question of mental illness. The first trial seeks to ascertain whether the defendant did carry out the illegal act of which he is accused. If he is found guilty, the second trial seeks to determine his state of mind at the time, in relation to the established criteria for legal responsibility.

These variations in legal procedure throughout this country affect only a small fraction of the criminally accused. Several efforts have been made to pass legislation with wider applicability. A few states have followed the legislative example set down in the American Law Institute's Model Penal Code.

In 1959, for example, the Vermont legislature enacted a law governing the determination of criminal responsibility which is a direct outgrowth of the Model Penal Code:

(1) A person is not responsible for criminal conduct if at the time of such conduct as a result of mental disease or defect he lacks adequate capacity either to appreciate the criminality of his conduct or to conform his conduct to the requirements of law.

(2) The terms 'mental disease or defect' do not include an abnormality manifested only by repeated criminal or otherwise antisocial conduct. The terms 'mental disease or defect' shall include congenital and traumatic mental conditions as well as disease.

Similar provisions have been incorporated into the laws of New York State and Illinois. The impact of the Durham, Currens, and Gorshen decisions has so far been confined mainly to the jurisdictions of the courts in which they originated. The concept of criminal responsibility has remained essentially unchanged since its initial delineation by the Legal Lords during the reign of Queen Victoria. Clearly, these defections from the McNaughten rule, coming as they do within a single decade after a century of neglect, reflect widespread dissatisfaction and presage a legal consensus certain to be more in harmony with contemporary social values and scientific concepts than are the century-old answers of the English Lords. Despite this more optimistic out-

look, the fact remains that certain crucial issues are unresolved.

The official legal formulas are probably less important per se in determining criminal responsibility than is commonly believed. The nature of the offense, the defendant's personality, the competence of the attorneys, and the emotional reaction of the jurors will affect the outcome of a criminal trial more effectively than the complexities of the legal interpretation of responsibility. This implies certain inevitable inequities which our legal system has not yet taken sufficiently into account.

An adequate psychiatric examination is an essential prerequisite for a valid psychiatric judgment. In fact, however, the great majority of those persons who have been accused of criminal behavior are too poor to afford prolonged and intensive psychiatric study. Three decades ago, Massachusetts introduced the pioneering Briggs Law, which authorized the state to provide psychiatric examination of all men indicted for criminal felonies. This procedure has not been universally adopted throughout the United States, although trends in this direction have become increasingly evident. Massachusetts has continued to develop the psychiatric branch of its legal structure. California, New York, Illinois, Ohio, Wisconsin, and New Jersey have improved their techniques for ascertaining the presence of mental illness in those individuals who have been accused of antisocial behavior under their respective criminal codes, and these states have modified their pre- and post-trial psychiatric examinations for this population.

There has been an excessive emphasis on topics relating to responsibility for criminal behavior as a point of interaction between law and psychiatry. For many, it has become an emotion-charged *idée fixe*; others are preoccupied with its moral implications. All this leaves too little time or energy for other equally significant joint problems of law and psychiatry. But we cannot escape this redundant dialogue until we resolve it. This repetitious colloquy will end only when there is individualization in imprisonment, probation, and parole; when the psychiatrist becomes the diagnostician before the trial and the therapist afterward, rather than the instrument of social arbitration during the trial; when prevention by punishment and amenability to treatment are sensibly assessed in individual cases and human beings are no longer treated as hypothetical statistical entities.

Legal Procedure

Competence to stand trial. In the Anglo-American jurisprudential system, an accused person has the right to consult with counsel to ensure fair treatment under possibly hostile conditions. Recent decisions handed down by the Supreme Court, reversing the convictions of men who were unable to afford the services of an attorney and whose rights, therefore, were not adequately protected, reflect increasing concern with

this issue. However, even when a competent defense attorney is available, he cannot provide an adequate defense unless the defendant is intellectually and emotionally capable of cooperating with him by providing relevant information and by discussing alternative courses of action, in order to determine an optimal legal defense. When an accused man, because of intellectual deficiency or serious psychopathology, cannot advise, inform, discuss, and consult with his attorney, he is deprived of his day in court, according to Anglo-American tenets. For justice is presumed to be the legal outcome of a conflict between opponents of equal capacity; only then can the same rules of legal combat be sensibly applied to both.

Ironically, this crucial pretrial determination of competency to stand trial is least understood by psychiatrists. This issue has probably been the cause of more hardship and injustice than the more dramatic and acrimoniously disputed issue of legal responsibility. The judge usually has greater latitude in determining competence to stand trial, as opposed to the hotly challenged and highly articulated issues of responsibility, which are resolved in court proceedings, before spectators or reporters. The judge's instructions to the examining psychiatrist tend to be diffuse and ambiguous. Most psychiatrists and not a few judges confuse the defendant's competence to consult with counsel with his legal responsibility.

But even when such pretrial decisions do not suffer from these artificial impediments, their effects are unpredictable. Although the accused has been arrested and may have been indicted, he has not been found guilty of any crime. The pretrial decision relates to the fact that presumably one day the offender will stand trial to determine whether he actually did carry out the illegal act of which he has been accused, and to his ability to protect his rights adequately under such circumstances. In addition, the trial will ascertain whether, at the time of the alleged crime, the defendant's psychological state satisfied the legal criteria of intent and *mens rea*, which would make him responsible, culpable, and punishable in the eyes of the law. Obviously, there is no justification for a trial if the answers to these questions are obviously negative. The severely disturbed defendant is likely to be sent to a state mental institution without trial, until the superintendent of that institution is able to testify in court that, in his expert opinion, the defendant has recovered from his mental disability to the degree that he is competent to consult with counsel in his own defense. Although the law requires that he must be considered innocent until proven guilty, such a person is imprisoned in institutions for the criminally insane despite the fact that he may not have been brought to trial to determine his guilt. In most states, the public mental hospitals have a special subdivision where such persons are confined, and where they are frequently exposed to more stringent restrictions than

would be the case if they were actual prisoners or committed psychiatric patients.

Moreover, the reward for getting "cured" is a criminal trial. If a patient has been accused of a serious crime, the superintendent usually does not allow the patient to leave the grounds without court permission. The patient is thus deprived of the opportunity for graduated experiments in using his freedom which are an integral and essential part of meaningful psychiatric care. Often, he is simply lost in the twilight zone, as yet undefined, between the rites of punishment and the rituals of therapy. And there he is likely to remain. It is improbable that either the district attorney's office or the judge's chambers will initiate inquiries concerning his mental status. Thus, with the passage of time, under the pressure of more immediate concerns, his dossier will move further back in the government files.

Juvenile Delinquency

Socioeconomic determinants. Slums have long been considered a malignant factor in the etiology of delinquency. In fact, however, the gangs which are characteristic of such slums offer the slum youngster a simpler and cruder, but more manageable, social organization than the vast and impersonal structure of the dominant community. These smaller, loosely knit groups, with their tough leaders and fairly obvious goals and rewards, provide a welcome alternative to the disorganized and apparently aimless public chaos of community life and the private dangers of inadequate intrafamily relationships. Many of these youngsters are at war; they are soldiers in the ranks of their culture, their class, and their caste, at war against the dominant culture of the elite.

These adolescents have been called rebels without a cause, but they do have a cause, even if most adults deny it and they themselves are unaware of it. In part, that cause is the classic precondition of all revolutions: the glaring inequities between those who rule and those who are ruled. It is a concomitant of a sincere struggle to achieve a democratic society, to realize the ideal or the myth that, in a free enterprise economy, everybody has an equal chance. For it is characteristic of our society that success, wealth, and fame are held to be attainable by all men and are depicted as the highest goals to which man can aspire. Yet under our present social system it is impossible for large segments of our population to achieve these goals through socially and legally acceptable channels. This circumstance, which Durkheim labeled anomie, is a precondition for the precipitation of despair of achieving the social status associated with these goals in some, and for desperate attempts to acquire them in others. For still others, the alternative solutions are emotional disturbance or delinquent activities.

The social causes of psychopathology and social offense are real. Only a small minority of the population who are socially and economically deprived enlist

in the delinquent army of rebellion or withdraw into psychic alienation. Because the community in which these subjects live is a common ocean of despair, only by close observation of the family interaction and the individual can we explain why this minority succumbs, while the majority do not. Certain associations cannot be avoided. The child who comes from a family which has somehow preserved its cohesiveness, and in which both the mother and father have maintained a reasonable balance of affection and of discipline, is less likely to become delinquent than the youngster who is raised in a home in which relationships are loose and distant, and in which punishment is too severe and unpredictable or affectionate overindulgence is the rule. The physiological status of the youngster, whether he is robust and active, for example, or relatively inactive, may affect his prognosis. The existing evidence would indicate that in socially deteriorated areas the vigorous boy with an athletic, mesomorphic body build is more likely to get into trouble with the law.

Delinquency is not associated only with slum environments and low socioeconomic status. It is not unknown among middle class families from "respectable" neighborhoods. Such middle class delinquency has recently received more attention. There are wide differences in the explanations of delinquent behavior in such an environment. There is reason to suspect that in some of these cases the youngsters are carrying out socially deviant or offensive acts because they have been unwittingly encouraged to do so by their fathers and mothers, who are shocked and ashamed when the delinquency comes to light. Most of these parents are solid, conforming citizens. They have unconscious psychopathological tendencies toward delinquency, which they transmit to their youngsters in a variety of ways of which they are unaware. These are the fathers who flex their muscles conventionally and openly when their sons make varsity; these are the fading mothers who preen a bit when their adolescent daughters are deluged by invitations to the prom; but, on another level, through the underworld of the unconscious, they may be sending hidden but potent affirmative signals to their children to carry out acts which titillate them, even though they consciously reject such acts, and even while they send loud but ineffective negative signals.

Legal and social offenses, then, are acts of specific people who live in particular environments, who respond to and arouse punitive responses among powerful elements in the community. Community response to delinquency merits our special consideration. A process of social selection is operative in the determination of criminality which is of crucial importance. An adult who has committed an illegal act must be detected, selected, and go through a complicated social and legal ritual before he is labeled "criminal." We were interested in exploring the crucial implications of this process with respect to children.

We started with two groups of children between the ages of 5 and 10, who were comparable to each other in every possible way, including the fact that each had behaved in a particularly naughty and socially undesirable manner. Mainly, they had stolen things, broken windows, stayed away from school, or set fires. They differed only in that the first group had been referred to child guidance clinics for treatment, and the remaining half, the second group, had been hailed before juvenile court. How had this happened? We found that this difference in disposition had very little to do with their backgrounds, acts, or personalities. These were all lower class children. (It is very rare for middle class children to be sent to a juvenile court.) In these cases, this crucial variable depended on which institutional affiliation was most congenial to the referring adult. Policemen always sent children to the juvenile court; indeed, most policemen did not even know that a child guidance clinic existed in the community. Those few who did had no idea what it did. Conversely, social workers referred children to the clinics. They knew about the juvenile court but preferred not to acknowledge it. Generally, teachers sent troublesome children to the clinic, but occasionally they referred them to the court.

As far as the child was concerned, although his behavior was a factor, chance was the primary determinant in referral and therefore in whether he would go to a doctor, who would treat him as though he were sick, or to a court, which would, however progressive, tend to identify him as *bad*. This lesson, learned so early and under such adventitious circumstances, was likely to have far reaching implications. As far as the delinquent was concerned, the sociolegal response to his acts had an arbitrary quality. The adult values which these decisions reflected were mysteries to the child. They were generally alien to the expressed intent of the law, which is to promote equal justice.

Juvenile delinquency and mass media. Of those factors which are most frequently cited as the cause of juvenile delinquency, inadequacies in family relationships are most commonly invoked. However, juvenile delinquency has also been attributed to the community environment, including the content and form of the mass media. In one investigation of adolescent, young adult, and mature delinquents, we studied the newspaper accounts of their cases during the trial as well as the trial records when available to determine whether there had been any consistent variations in the way the communication media and the courts reacted to different sorts of crimes and to personality differences among the alleged offenders. There was ample evidence that responses did differ, and these differences were reflected in the discrepancy in the amount of space allotted to reports of the case in the newspapers, in the size of headlines, and in the moral tone adopted in articles devoted to one type of crime as compared to another. These differences affected community attitudes toward the delinquent and contributed to or deterred rehabilitative efforts on his behalf. The "publicity" given a particular crime is sometimes so attractive that the vulnerable youngster may be motivated to emulate the "hero-criminal."

Television has come under stringent censure if not

scrutiny. Certainly, any imaginative production may provide models and perhaps serve as the precipitating factor in the delinquent behavior of certain children. Psychopathic youngsters, for example, whose identifications with meaningful adult figures have been seriously impaired, whose self-censoring and self-governing mechanisms are defective, and whose object relationships are shallow and transitory are likely candidates. Unsure of their own image, distant in their relationships, but poised for rebellion, they may use the television criminal as their model and be guided by his example into delinquency. However, for the average youngster whose environment is not pathogenic, there is little evidence that television content is an important causative factor in childhood delinquency.

The psychiatrist in juvenile court. The psychiatrist who deals with juveniles in any sort of legal difficulty must develop perspectives appropriate to these special conditions. It is generally recognized that the traditional use of conventional child guidance techniques is inadequate under these circumstances, although they have not yet been replaced.

Children may be referred to juvenile court, not only because of harmful acts which they have carried out but ostensibly to protect them from harm. For example, the psychiatrist might be called upon to advise in cases in which a child has been sexually accosted. In that event, he must be alert to the possibility that the child's description of sexual seduction or assault by an adult may be a product of misinterpretation, misunderstanding, or projected day-dreams. If it is reasonably certain that physical erotic interaction did in fact occur, he must assess not only the activity of the adult, but the child's seductiveness, as well as his participation, enjoyment, and efforts to continue the relationship. The emotional cost to a child must be the primary consideration. A child who has been sexually excited prematurely may be burdened in his later psychosexual maturation. However, interrogating the child for the purpose of obtaining evidence, through court procedures or even in the privacy of the judge's chambers; undue publicity; and punishment of the adult for acts which the child actually found gratifying or had exaggerated in the retelling may superimpose additional burdens of anxiety, guilt, and shame on the already existent difficulties. These may be more potent precursors of psychopathology than the original traumatic incident. Ignored, or treated adequately within the child's world, such an experience may be successfully repressed, sublimated, or integrated into the conscious ego. If the experience is set within a hyperbolic, public and semipublic legal, punitive, retributive ritual, the child's capacity for developing adaptive defenses may be significantly lessened.

In any juvenile court cases, the psychiatrist should become familiar with the world of his young patient. Frequently, the psychiatrist will be called upon to assist a child whose environment, background, and rela-

tionships lie outside his experience and which, therefore, may be more difficult to understand.

Civil Competence

Definition and criteria. Although problems of criminal responsibility and competence to stand trial are the center of a continuing dialogue between the professions of psychiatry and law, the determination of responsibility and competence in civil cases is qualitatively greater in scope. Every juristic act presumes that the participants are mentally competent to make appropriate decisions. Just as persons under a certain age are not responsible for any criminal acts they may commit, the law denies this segment of the population the power to make certain contracts, to marry, and to enter into other civil-legal relationships, on the grounds that their age is inconsistent with the presumption of mental competence, and hence civil responsibility.

Adults are generally presumed competent to handle their own affairs unless evidence is produced to the contrary. Unlike criminal responsibility, which uses identical criteria without regard to the nature of the offense, civil responsibility is adjudged in terms of the degree of mental competence appropriate to the particular act in question. The criteria to ascertain whether an adult is competent to be the guardian of a child are different and more demanding than the criteria to determine whether he can dispose of his own possessions by making a will.

Some states require medical tests to ascertain the possible presence of venereal disease in couples who wish to marry. Some consider a history of epilepsy relevant to the question of marriageability and refer them to neuropsychiatrists for diagnosis and advice. Therapeutic abortion may be carried out in some jurisdictions if, in the opinion of one or two psychiatrists, there is a possibility that the pregnancy might result in serious psychical or physical harm to the parturient woman. Some 27 states now have laws permitting sterilization of certain classes of persons, either because they have been adjudged socially dangerous sexual psychopaths or because they have serious pathological conditions which are considered to be genetically transmitted.

Testamentary capacity. The ownership of property is a basic right under our system of government. By extension, we are granted the right to dispose of that property as we wish, as long as the rights of others are not violated in the process. Wills are, of course, the main instruments for controlling such allocation after death. Frequently, wills give rise to family conflicts and the capacity of the deceased to have executed a will may be challenged. Court action of this nature may even be taken during the lifetime of the person whose testamentary capacity is being questioned. Most commonly such suits are allegations of senile deterioration, chronic intractable psychosis, mental retardation, or incapacitating chronic alcoholism. However, the psychiatric assessment of such patients raises

complex problems. Since senile changes may fluctuate, for example, the individual's state of awareness and alertness may be different at the time of examination than it was at the time he wrote his will.

Cases in which the psychiatrist is asked to make a retrospective assessment of the mental state of the testator after his death, which are more common, present problems of another nature. In such cases, it should be borne in mind that the psychiatrist's function is not to evaluate the decedent's general mental condition, for the severity of his mental illness or deficiency is relevant only to the degree that it may have impeded his ability to recall the extent of his property or his awareness of the natural objects of his bounty.

In questions of civil competence, social policy favors the individual. In a society organized around family patterns and private ownership and in which social stability is fostered by transmission of property within the family, an inquiry into the testamentary capacity of a man whose will includes such a provision is directed not only at the author of the will; such an inquiry also challenges this powerful sociolegal tradition.

In general, however, whether the "competence" relates to wills, contracts, or the making or breaking of marriages, the fundamental concern is the person's state of awareness and his capacity to comprehend the significance of the specific subject of the particular commitment he was making—at the time he made it. In other words, the two most relevant questions are, first, whether the participant understood the nature of a specific act and, second, whether he was aware of his duties and obligations in connection with that act. A marriage can be annulled if, according to these criteria, one of the participants was incompetent at the time they entered into the marriage contract. Competence to initiate divorce proceedings may be similarly assessed on the basis of cognition and awareness. In many states, severe, incurable mental illness of one of the partners is considered grounds for divorce.

Civil issues involving questions of mental competence reflect the congruence of legal and psychiatric concerns and the range of such concerns far more effectively than more dramatic criminal issues. Evaluation of mental states may be necessary for purposes ranging from the execution of contracts, deeds, and wills, to marriage, divorce, annulment, and guardianship of minors, from citizenship to military service. Because the question of competence relates to every phase of normal existence, the law wisely guards its precedents zealously: such competence is always presumed unless there is strong evidence not only of incapacity, but that this incapacity affects the particular issue and is potentially harmful to the individual.

Psychiatry and Law: An Overview

The phrase, "forensic psychiatry," is an old one, and it connotes the rhetorical tactics of the courtroom. But, as we have seen, psychiatry's concern with the law

extends far beyond these limits, for every psychiatrist is constantly dealing with patients whose feelings of guilt, shame, dependence, or unresolved conflict have been influenced, to a significant degree, by the legal environment in which he lives and in which he grew up. The law's concern with the mental status of those individuals accused of offenses against society has preoccupied jurists for centuries. No final solution is yet in sight; moreover, it seems self-evident that there can be no ultimate resolution to this question. Just as human anatomy is the product of biological evolution, human social organization is the product of cultural evolution. The legal codes are part of this cultural evolution, which is a never ending process. In time, the legal attitude toward the criminal may undergo basic changes, and, concomitantly, the psychiatrist's function at a criminal trial may become less significant than his efforts to prevent the psychosocial maladjustments which lead to criminal behavior.

There is no forensic psychiatry as such; psychiatry is not concerned with legal rhetoric or courtroom debate. Psychiatry's sole concern, in relation to the law, is the mentally ill (or healthy) individual whose behavior has aroused the anxiety, anger, and revenge of the community, which, in turn, has reacted through the rituals of the law. There is an urgent need for this kind of psychiatric concern, but this sense of urgency does not arise from the common misconception that there has been an increase in man's destructive, aggressive, and polymorphous promiscuous tendencies. Modern man is no more erotic, brutal, or unscrupulous than were his ancestors. Rather, the disturbed individual now has the capacity to extend his range of activity beyond the boundaries of his family and community and has thereby extended his spheres of human impact. His biosphere has been expanded. And, concomitantly, the expansion of our sociosphere has made us more vulnerable to his influence.

It follows that social contagion of delinquency and the epidemiology of mental illness are appropriate areas for psychiatric concern. Disorganized communities and fragmented families predispose to emotional distress. An environment in turmoil will find its chaos reflected in the inner conflicts and delinquent acts of its inhabitants. Of greater potential value than his role in ascertaining the mental state of offenders is the psychiatrist's contribution toward the prevention of the overt manifestations of personal conflict which may damage the life of the delinquent, as well as the community in which he lives. By the same token, positive changes in the law can serve to promote not only social stability, but psychic health as well, because a sense of justice is an essential prerequisite for both. It is an axiom that harmful legal experiments degrade politics and government and the personal psychological integrity of its citizens as well.

This discussion has been based on concepts derived mainly from psychiatry. However, this need not imply a restricted viewpoint. The goals of psychiatry are

therapeutic, but psychiatry is biological in origin, scientific in method, and individual in its concern. Some of these criteria apply to other specialties as well, but in combination all apply only to psychiatry. Like religion, psychiatry has values; like politics, it is concerned with the role of power and the management of men; like law, it concerns itself with structure, rituals, and functions relating to serious dislocations between the individual and the group; like psychology and sociology, it has developed methods of study; and, finally, like education, its goals are growth, change, individuation of personality, and generalization of major values. Psychiatry combines the humanistic and healing traditions of medicine and the disciplined empiricism of biology. It shares the awareness of both that the anatomy and physiology of the human animal comprise the primary data of his being, whether he is viewed as an individually reacting organism or as part of social patterns of interactions.

In recent years, the pattern of diverse and often discrepant studies of "crime in the mass" by sociologists, comparative law by lawyers, and the relationship between individual psychodynamics and genetic and somatic factors by psychiatrists has shifted somewhat toward hopeful advances in interdisciplinary collaborative efforts. We seem to be moving away from separate and disparate studies of sociology, of comparative law, and of individual psychodynamics. During the past decade there has been an increased rapprochement among these disciplines with respect to the causes and consequences of socially deviant behavior. Institutes have been established in academic settings in which social scientists, lawyers, and psychiatrists are attempting to solve sociopsychological problems in which they share an interest.

American universities have also initiated rapidly expanding programs of collaborative undertakings between psychiatry and law. The psychiatrist is being called upon to play an increasingly important part in every phase of community deliberation and action. A National Institute of Social and Behavioral Pathology, dedicated to the comprehensive attack on all phases of the strategic problems common to psychiatry and law, might be a practical and effective response to the social problems with which we are confronted. Many of the techniques and areas of psychiatric and behavioral science research lend themselves to investigation of compelling legal problems, as well as psychopathological questions. These include studies of the participants in the legal process, of the sanctioning methods employed by the community to accomplish its objectives, of the factors which affect the degree of popular conformity (or nonconformity) to legislative policies, of the process of struggle and agreement in the community, of professional education and development. Detailed knowledge of the formal and effective decision institutions of the community has an essential bearing on the relationship between legal procedures and the

increase or decrease in mental disease, as well as its form and content.

In 1959, the British Parliament passed a Mental Health Act which surpasses all but the most advanced legislation enacted in this country, in that it removed the residual stigmata of centuries from the mentally ill person. In Great Britain such patients are treated with the same concern for their welfare, and with the same emphasis on their resuming, as soon as practicable, an appropriate role in the community, as has long been the accepted medical goal for the physically ill. Local health administrators are empowered to provide hostels for patients whose illness does not require hospitalization, and for recently discharged patients who are not yet ready to assume full autonomy. Sheltered workshops employ persons who are unable to work effectively in private industry or business but who can contribute useful skills in a less competitive milieu. Other local community centers are equipped to train disturbed youngsters, to provide homes for aged incompetents, and to give counseling and psychiatric supervision to patients during their transition from hospital to home. Treatment of the mentally ill, by this act, need no longer be confined to special "asylums" but may be carried out in any properly equipped general hospital. Although certain classes of psychiatric patients may still be compulsorily certified or committed, such certification is based on the medical opinion of two physicians, one of whom must be trained and experienced in psychiatry.

In 1952, in the United States, the Public Health Service and the National Institute of Mental Health prepared a similar "Draft Act Governing Hospitalization of the Mentally Ill." Unlike England, because of our Federal system, such an act cannot be enforced throughout the entire country, of course. However, a law derived from the Draft Act was passed by Alaska while it was still a federal territory, and several states have used it as a model for their mental health legislation. Clearly, it represents a major advance; yet the basic objectives of the Draft Act were stated as early as 1869 by the pioneer of American medical jurisprudence, Isaac Ray:

In the first place, the law should put no hindrance in the way to the prompt use of those instrumentalities which are regarded as most effectual in promoting the comfort and restoration of the patient. Secondly it should spare all unnecessary exposure of private troubles, and all unnecessary conflict with popular prejudices. Thirdly, it should protect individuals from wrongful imprisonment. It would be objection enough to any legal provision that it failed to secure these objects in the completest possible manner.

The Draft Act comes as close to fulfilling these objectives as possible at this stage of our knowledge: it provides for a more medically based approach to the mentally ill while increasing the protection of such persons from violation of their civil and constitutional rights and liberties.

There are other indications of progress. The Ameri-

can Medical Association has recommended increased interdisciplinary training in law and medical schools, and in governmental facilities, as one of several efforts toward improved medicolegal communication. And, as mentioned earlier, it urged that the psychiatric offender, specifically the alcoholic and the drug addict, be treated medically rather than punitively. It has emphasized the need to free psychiatric patients from legal restrictions. Neither voluntary procedures nor those which require temporary commitment need rob the patient of his civil rights, any more than hospitalization for the treatment of infectious and contagious disease. The American Medical Association has also recommended that the criteria of legal responsibility and the psychiatrist's courtroom testimony be more responsive to contemporary knowledge.

The Model Penal Code, sponsored by the American Law Institute, ranks with Action for Mental Health, the Report of the Joint Commission on Mental Illness and Health, as a major document for those concerned with the mental health of the community. However, these plans are models for action and, as yet, lack the force of official power. Their effectiveness depends upon their implementation: if they are carried out, the psychiatric, medical, and ethical level in this country will be elevated.

Chapter 49

Military Psychiatry

49.1 • • •

JOHN M. CALDWELL, M.D.

Introduction

The problem of emotional disorders has plagued the military since the beginning of recorded history. In the Seventh Chapter of Judges, a procedure for the selection of men "fit" for combat is described: Israel and Midian were preparing for battle, and the Lord said to Gideon, "The people that are with thee are too many. . . . whosoever is fearful and afraid, let him return and depart." Twenty-two thousand men departed, and 10,000 remained. And the Lord said, "The people are yet too many." Thus, the 10,000 men who remained were finally reduced to 300, who defeated the Midianites. On the basis of military experience in World War II, i.e., the percentage of draftees who were rejected by the Armed Services on psychiatric grounds, psychiatric casualties during and immediately following combat, and, finally, the number of men who developed psychoneuroses after their return to civilian life, the number of men who were deemed suitable for military life by the Lord and Gideon, namely, 300 out of a total of 32,000, does not seem out of line. However, modern wars are not fought by a select few, but by large numbers of men.

Current concepts. Progress and changes in military psychiatry were reported during World War II and have been reported since by Menninger, Caldwell, and others. There is no question that in the past mental and emotional problems have interfered with the success of crucial military engagements. In fact, it has been suggested that emotional and mental problems have been the greatest single cause of military ineffectiveness and loss of manpower. This is no longer true today; moreover, owing to the increasingly effective methods employed for the control of psychiatric disorders, it is not likely that military efficiency will be impaired by psychiatric factors in the future. A report issued by the Group for the Ad-

vancement of Psychiatry on preventive psychiatry in the Armed Forces is relevant in this connection:

It may be stated that concurrent with the institution of a broad program of preventive psychiatry in the Armed Forces the following has occurred:

1. There has been a decrease in the hospitalization of identifiable psychiatric disorders both in war and peace.
2. There has been a continuing decline in medical separations for psychiatric illness.
3. There has been no corresponding increase in loss of manpower through administrative channels, or through medical separation for nonpsychotic illness when corresponding periods of time are involved.
4. There has been a decrease in the number and rate of disciplinary confinements.

Data accumulated from other sources confirm these findings. Thus, the prediction that, following the Korean War, the Veterans Administration would be required to care for an increased number of psychiatric cases has not been fulfilled.

Preventive Psychiatry in the Armed Forces

Definition. Logically, a discussion of preventive psychiatry should begin with a delineation of just what is being prevented. Is it the aim of a preventive program to produce mentally healthy individuals, and, if so, what is mental health, or ill health? In one definition, mental health is described as the capacity to live harmoniously in a changing environment. The World Health Organization has defined health as the individual's positive sense of physical, mental, and social well-being, rather than the mere absence of disease or infirmity. And it is to this goal (i.e., to the physical, mental, and social well-being of the personnel under their care) that the preventive efforts of military psychiatrists have been directed. (On the other hand, presumably, ill health would be the converse of the definitions given by the World Health Organization.) Depending on the definition of health and ill health, it may well be that a preventive program would consist of the promotion of those factors which are considered to contribute to the health of a specific group of individuals and, concomitantly, to the prevention or elimination of various factors which are conducive to ill health, if these factors can be identified.

Inevitably, such efforts will be complicated by the ambiguity of such criteria as "normal," "median," "average," "customary," and "culturally determined." By definition, the behavior of the "normal" individual is consciously determined, for the most part; in addition, such an individual is flexible enough to adapt to a changing environment and life situation; and, finally, his behavior can be modified by experience. Should this concept of "normal" behavior determine the structure and goals of a preventive program? Or should such a program be based on the concept of the "adjusted" individual, i.e., one who is reasonably well adjusted to his environment and its demands? Or will a preventive program be most effective if it is conceived of in pragmatic terms, i.e., if it derives from the concept of the "effective" individual who, while he may or may not be "well adjusted" or "normal," is able to fulfill his stated purposes and goals? "Normal," "adjusted," and "effective" are not necessarily equivalents, of course. Clearly, however, they are all related, in varying degrees, to the presence or absence of mental health. Accordingly, indices of the noneffectiveness of military personnel, such as the number of men who go AWOL, the rate and frequency of hospitalization, court martials, and various service discharges, do reflect the effectiveness of military commands; similarly, the effectiveness of the command as a social unit may be evaluated in terms of individual adjustment. Such indices have been used by the military to evaluate various preventive measures and programs.

Precipitating factors in psychiatric illness. Under the leadership of Brigadier General William C. Menninger, who was attached to the office of the Surgeon General as Chief of the Neuropsychiatry Consultants Division during World War II, a new approach was attempted to the problem of psychiatric disability in the Armed Forces. The efforts of Dr. Menninger and his staff were based, in part, on recommendations made by Appel and Beebe, following a field study initiated in Italy in 1944. These authors discussed many of the findings derived from this study in a paper entitled "Preventive Psychiatry, an Epidemiologic Approach." The precipitating factors enumerated therein were persistent realistic danger, duration of exposure to combat, length of tour of combat duty, lack of incentives and rewards, leaks in evacuation screening, the replacement system, inadequacies in training and leadership, the role of command in the prevention of loss of manpower. In general, emotional breakdown was considered to be the result of an imbalance between environmental stress and emotional supports. Based on this impressive analysis, there were gradual changes in administrative policy, directives, and operations, but these changes were not generally accepted and instituted until the Korean War.

The functions of military command. As pointed out above, the majority of factors which de-

termine the mental health of military personnel are functions of command. In other words, the major responsibility for implementation of the principles of preventive psychiatry is borne by commanding officers. Military command can fulfill the obligation to ensure maximum utilization of manpower by providing, among other things, proper leadership, training, incentive and motivation, and such reclassification, reassignment, rest, recreation, and relaxation as are permitted by the exigencies of military service.

It is the duty of the staff psychiatrists who are attached to training centers, disciplinary barracks, divisions, armies, theaters of war, and higher echelons to be alert to policies, situations, and other factors which may predispose to, precipitate, or perpetuate neuropsychiatric disorders and to recommend appropriate measures for the alleviation or elimination of these factors. In brief, the officer in the front lines is concerned primarily with the effective performance of personnel under his supervision, inasmuch as it may be crucial to the success or failure of his mission. The average medical officer is usually concerned with the man only when he is physically ill. Thus it becomes the task of the psychiatrist to be ever cognizant of the total man, his personality, crises in his life situation, his job, his assets and liabilities, evidence of the effects of stress, and his need for additional support.

The Influence of Psychiatry on Current Military Policy

In future wars, different factors may be operative. But, based on cumulative experience through World War II, in the years from 1946 to 1950, numerous changes in Army policies and operations were instituted. Those changes which have special relevance for this discussion are described below.

Selection. In World War I, the rejection on psychiatric grounds was approximately 2 per cent, which would indicate that only those who were grossly unfit mentally and emotionally were rejected from service. As might be expected, large numbers of the individuals who were inducted into the Army subsequently became disabled by reason of psychiatric disorders.

In preparing for World War II, it was thought that it might be possible to prevent a recurrence of this situation by rejecting those draftees who were predisposed to psychiatric disorders (as well as those with demonstrable emotional illness). After this policy had been officially established, approximately 7 per cent of all draftees were rejected for psychiatric reasons alone; and an additional 5 per cent were rejected because their low scores on psychological tests were considered to indicate an inability to learn. Yet, despite this high rejection rate, at one point in 1943, more individuals were discharged from the service for emotional and personality disorders than were inducted.

A major policy reorientation was clearly called for. It was pointed out that the history of ability to function in civilian life could be presumed to indicate a capacity to function at some level within the military service. Accordingly, there was a major shift in emphasis from selection of individuals for service (i.e., combat duty), to the proper utilization of military personnel, depending on evaluation of their adaptive capacity, after they were in the service. In brief, rejection by reason of specific disease or named disabilities was deemphasized. And, during the Korean War, once again approximately 2 per cent of the draftees were rejected for psychiatric reasons.

Prediction of performance. The fact that a selection procedure based on a portended predisposition to psychiatric illness ultimately proved unworkable was due, in large measure, to the inability of psychiatry to make a significant contribution to predictive techniques. For obvious reasons, it was difficult, if not impossible, to establish criteria for future performance, when it was necessary to take into account an unknown training period, in an unknown situation, under unknown situational stress, with unknown emotional supports, for an unknown length of time. On the one hand, a lack of military effectiveness was found to be related to situational stress and interpersonal relationships, rather than individual psychopathology. On the other hand, obviously, individual psychopathology can, in itself, create situational stress and difficult interpersonal relationships. The issue was further compounded by the knowledge that many individuals with overt psychoneuroses or even a history of psychotic episodes performed in an outstanding manner under combat. These diverse considerations resulted in a shift, whereby military psychiatrists no longer focused on the identification of those abnormal personality components which caused military ineffectiveness. Their efforts were focused instead on making it possible for the "normal" man to adjust to an abnormal situation.

Hospitalization. At one time, according to military policy, a soldier had only two alternatives. He could be either on full duty status or in a hospital. In time, it became apparent that while a temporary emotional crisis might interfere with a soldier's ability to perform with maximum effectiveness on full duty status, in general, the aggravation of neurotic symptoms or personality conflicts did not require hospitalization. In fact, in such cases, hospitalization could contribute to further ineffectiveness. Therefore, the maximal use of out-patient treatment facilities in army posts, camps, stations, and during field training and combat was advocated instead. Ideally, the widespread availability of psychiatric facilities and personnel would enable the soldier who was undergoing a transient, mild emotional disturbance to remain on full duty status. The development and widespread use of Military Mental Hygiene Clinics has been well described by Perkins. Finally, it is true that the per-

centage of beds required for psychotic patients has remained relatively constant. Increases can be attributed to the increased number of servicemen, rather than to more unfavorable environmental situations or stress.

Discharge. Military discharge is justified only when the soldier's inability to perform any military assignment has been clearly demonstrated. A medical discharge is processed only after maximum treatment and rehabilitative measures have been fully utilized. Those individuals who incur a disability in the course of their army service which will restrict their civilian activities will, of course, receive a medical discharge. But applications for discharge because of an inability to adapt to situational or environmental factors or because of "unfitness" for service due to the presence of undesirable personality traits are processed through administrative channels.

Combat. Assignment to combat is probably the one assignment for which there is no comparable civilian occupational specialty. However, there is no aspect of military duty that does not contribute in some way to ultimate combat effectiveness. Nevertheless, it was recognized that special emotional supports must be provided, as delineated below.

Training. Men must be adequately trained in the use of their weapons and must have confidence in their ability to perform effectively in combat. However, the former training policy of "kill or be killed" has been discarded as both ineffective and psychologically damaging.

Assignment. The effective utilization of men requires that assignment be based on training and aptitude, not only on military need. Just as World War I demonstrated the importance of considering aptitudes for the effective utilization of manpower, World War II demonstrated that the consideration of attitudes was equally important as a means of ensuring adequate performance.

Replacement. Replacement in combat is made on a group, rather than an individual basis. In other words, a "buddy" system of assignment to combat areas has been instituted. Before he goes into combat, each man is given an opportunity to familiarize himself with his new unit. The fact is that men do not fight well in strange units or under unfamiliar officers. Individuals are also rotated from combat at periodic intervals for rest and recreation.

Personnel policies. Personnel policies must reflect an awareness of the dignity and importance of the individual. The individual is the most important single asset in any army; consistent with his capabilities and the needs of the service, his desires will be given primary consideration. There has also been increasing recognition of the need for measures to facilitate and enhance communication, not only through the chain of command from the top downward, but from the lowest ranking soldier upward to those empowered to make decisions.

Domestic problems. The impact of crises on the homefront, such as death, illness, marital desertion, divorce, and the devastating effects of "Dear John" letters, is recognized; and efforts are made to deal appropriately with the effects of such crises.

Identifiable emotional supports

Leadership. As mentioned above, the ineffectiveness of military personnel is often related to inept or inefficient leadership, as well as other environmental factors. Unfortunately, techniques for the selection, control, and relief of officers still leave much to be desired.

Group identification. The importance of group identification has long been recognized; nevertheless, it is sometimes ignored. Yet it is the support of the group and the sense of belonging to a group which often sustains the soldier in combat after other supports have fallen away. Obviously, it is more difficult to identify with a unit that is designated only by number.

Orientation. Since the Revolutionary War, military leaders have identified certain characteristics unique to the American soldier. For example, typically, he wants to know why such and such is necessary before he is willing to take orders or perform assigned tasks. Therefore, adequate orientation to immediate and long range objectives is necessary.

Motivation. The importance of motivation cannot be overestimated. The factors which produce motivation include rewards and incentives, and various conscious and unconscious factors which determine underlying attitudes and morale. There is no question but that underlying attitudes influence nonverbal behavior. This has been demonstrated conclusively by Stouffer, who evaluated a unit's attitude toward combat while in training a year before D-Day and again immediately prior to D-Day. In the investigations he conducted 60 days after D-Day in the European Theater, Stouffer found that units which had previously manifested good attitudes toward combat suffered 30 per cent to 60 per cent fewer nonbattle casualties than did those units whose attitudes toward combat had not been so good.

Education in mental health. An important emotional support for everyone is education in mental health, including mental hygiene and the dissemination of information regarding the psychodynamics of fear, panic, rage, etc.

Religion. Facilities for religious services and the aid, counseling, and comfort provided by chaplains constitute another essential emotional support.

Prevention

In essence, military psychiatry is the practice of preventive psychiatry to the maximum extent possible in the military community. Moreover, the principles and practices of preventive psychiatry are applicable, to a greater or lesser extent, throughout

the Department of Defense, and in other governmental agencies as well.

Primary prevention. The goal of primary prevention is to reduce the incidence of a given disorder in a community or population or, more specifically, the rate of occurrence of new cases. With specific reference to psychiatry, the concept of prevention presumes the view of emotional and mental disorders as "reactions," which do not represent an organ illness but a person illness which occurs in a social and interpersonal setting. An example of the application of the principles of primary prevention in the military community is summarized below.

As part of a field study currently under way, emotionally "vulnerable" individuals are interviewed in an effort to identify specific external stresses and ascertain the presence or absence of emotional supports operative in the stress-provoking situation.

The psychiatrist's particular competence in this area stems from his knowledge of human motivation, of the unconscious determinants of behavior, and from his understanding of the importance of maintaining a balance between external stresses and supporting factors in human adjustment.

Concomitantly, attempts are made to introduce changes, through administrative channels, with the aid and collaboration of personnel at other levels, which will alleviate the previously identified external stresses and/or provide necessary emotional supports.

The final step involves the translation into general military policy and directives of the knowledge gained from individual specific studies and situations and from the demonstrated effects of the modification of specific external stresses and the promotion of specific supports. (It is understood, however, that in any area characterized as a locus of mental disorder, field studies would still be necessary to identify the presence of specific stresses and attest to the absence of required emotional supports.)

As mentioned earlier, the effectiveness of preventive efforts can be measured by statistics reflecting the incidence of atypical behavior among noneffective personnel. During World War II, for example, a "morale index" was developed consisting of the rates for AWOL, venereal disease, sick call or hospitalization, and court martials (see Figure 1).

Principles of primary prevention

Epidemiological considerations. It is essential, of course, that a program of primary prevention take cognizance of the fact that a psychiatric disorder, like a nutritional deficiency disease, has epidemiological characteristics.

Emotional needs. If certain needs are not supplied by the environment or culture, then the individual may become mentally or emotionally ill. These needs will vary, depending on the individual's stage of development. Erikson has listed the characteristic nu-

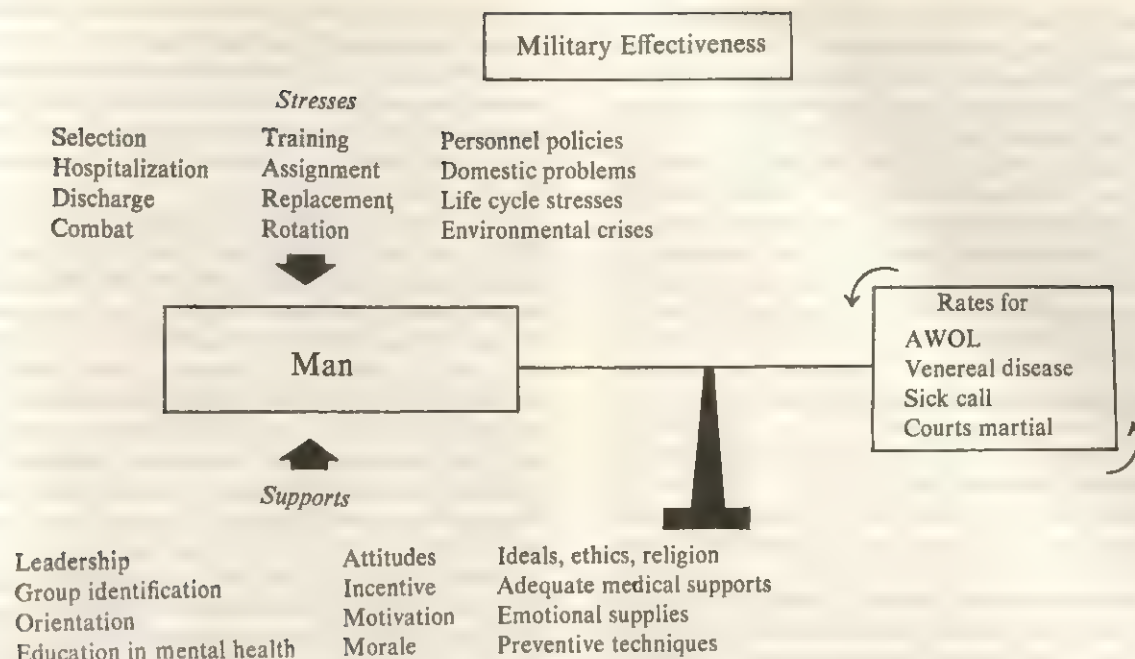

FIGURE 1. Preventive psychiatry. An individual's adjustment or effectiveness may be related to a balance between various stresses and emotional supports, as reflected in rates or indices measuring inadequate performance. Health is a state of physical, mental, and social well-being and not merely the absence of disease or infirmity.

clear conflicts for each stage of psychosexual development as follows: (1) trust versus basic mistrust, (2) autonomy versus shame and doubt, (3) initiative versus guilt, (4) industry versus inferiority, (5) identity versus role diffusion, (6) intimacy versus isolation, (7) generativity versus stagnation, and (8) integrity versus disgust and despair. Parenthetically, nuclear conflicts in the serviceman might be stated as (1) fear and cowardice versus courage and bravery, (2) guilt and shame versus pride and self-esteem, and, according to Bushard, (3) anger, frustration, and hostility versus "commitment" and "concurrence."

Maslow has enumerated a hierarchy of needs essential for human adjustment. They include (1) physiological needs for water, food, etc.; (2) needs for security and stability of expectation; (3) the need to give, as well as receive affection, to have a place in the group; (4) needs for self-esteem, prestige, etc.; and (5) the need for an opportunity to achieve or fulfill one's potentialities.

And, finally, in his recent volume on preventive psychiatry, Caplan has described emotional needs in still another framework: (1) Physical needs: food, shelter, sensory stimulation, exercise, protection against infection, trauma, chemical poisons. (2) Psychosocial needs: personal interaction and continuing relationships with significant people in the environment for the exchange of love and affection, asserting or submitting to authority, participation in joint activity, or independence in dealing with a task. Unfilled needs may be due to excessive manipulation by others or the interruption of a significant relation-

ship by illness, departure, death, or disillusionment. In this connection, Caplan has also emphasized the importance of providing help during periods of crisis, i.e., short term periods of stress related to death, illness, loss of a job or job change, accidents, surgery, admission to college, marriage, divorce, birth, parenthood, etc. (3) Sociocultural needs: customs and values, expectations of others. Conversely, Caplan stressed the negative effects of belonging to an unstable society, a minority group, or a deprived group.

Secondary prevention. Secondary prevention is designed to decrease the prevalence of a given illness in a population or community and/or prevent the progression of more serious manifestations of the illness by timely and effective treatment.

Apart from his duties as a staff officer, the activities of the military psychiatrist do not differ from those of his civilian counterpart. In his relationship to the psychiatrically ill patient, he employs the usual therapies as indicated, including individual and group psychotherapy, chemotherapy, organic therapies such as electroconvulsive treatment, work therapy, milieu therapy; and he utilizes the team approach of the psychiatrist, the psychiatric social worker, the clinical psychologist, the psychiatric nurse, occupational and recreational therapists, etc. Thus, the entire therapeutic armamentarium is at the disposal of the military psychiatrist and is made available where needed, either in hospital, mental hygiene clinics, or through the efforts of specific psychiatric treatment teams and units. The knowledge

that prompt and effective aid is available may also play a part in primary prevention.

Tertiary prevention. Tertiary prevention focuses on the rehabilitation of the ex-patient and on minimizing the residual defects of the illness or disorder. In a military setting, military personnel should be restored to maximum effectiveness before they are discharged from the service. If this is not possible, then the job must be taken over by the Veterans Administration. Depending upon the situation, convalescent hospitals may be useful for continuing therapy, retraining, and reeducation.

Special Problems of Military Psychiatry

Some situations, unique to the military situation, require special consideration.

Combat psychiatry. The success in handling emotional disorders in the combat area was due, in part at least, to the following:

1. A neuropsychiatric combat treatment plan has been accepted as official Army doctrine. This plan outlines the duties and responsibilities of theater, division, and hospital psychiatrists, as well as the establishment of a special combat neuropsychiatric treatment team to function in a neuropsychiatric treatment center. Under the provisions of the plan, the center was to be placed as far forward in the combat area as possible. Consequently, all patients suspected of an emotional disorder were funneled through the center before they were evacuated to the rear, and the center operated in other than the traditional hospital setting. Concepts, principles, and treatment procedures were all enunciated in appropriate army regulations, field manuals, technical manuals, bulletins, tables of organization and equipment, etc.

2. Individual treatment was directed to situational factors, with special focus on uncovering the individual's recent experiences involving fear, guilt, and anger. General measures included rest, food, explanation and reassurance, reliance on group loyalty, and environmental manipulation. Once he had acquired some experience, the front line psychiatrist was able to dispense with hypnosis, narcosynthesis, etc., with the result that he found that a direct psychotherapeutic approach was easier and more effective.

3. During the Korean War the concept of limited duty was revised. A personality profile was used in the psychiatric section of the physical profile and a grade of 3 indicated limited duty. However, individuals who had been judged unfit for combat by reason of an emotional disorder were not put on permanent limited duty but on temporary limited duty, with the expectation of their eventual return to combat duty. Reexamination at intervals of 30, 60, 90 days, etc., permitted the prompt return of a large percentage of these individuals to combat status, thus preventing the accumulation of numbers of unusable men. This procedure helped to preserve the individuals' self-

respect, as well. Men who returned to combat performed as well as did the new troops.

4. With the aid and collaboration of personnel officers, reassignments to combat duty were made as individual specific assignments, and, insofar as possible, the individual was reassigned to his former unit.

5. The combat psychiatrist himself was given specific indoctrination before a forward duty assignment in methods of rapid treatment; he was also reoriented to the greater importance of the group as opposed to the individual, and to the possibility of overidentification with the patient. It should be mentioned, in this connection, that the psychiatrist's feelings of guilt about returning his patient to combat—and potential danger—have been a persistent problem. It was apparent that the psychiatrist himself needed support from and communication with his superiors; yet often he was forced to work in relative isolation.

6. An educational program was initiated for front-line personnel to familiarize them with the manifestations of emotional disturbance and to enlist their cooperation in the management of such problems.

Apart from the use of these specific methods in combat situations, modifications have been introduced in training procedures, in methods of indoctrinating new personnel before they go into combat, in replacement and rotation policies, etc.

Brainwashing. During and after the Korean War, there was much discussion about the effects of brainwashing. According to those who have investigated such methods, the techniques used in brainwashing are reminiscent of Nazi police systems and Communist practices. The essential features of this method are isolation, deprivation, repetitive interrogation, threats, self-criticism, and group criticism. Prolonged exposure to such measures may result in mental dulling, depression, or even delirium, hallucinations, and delusions. According to Hinkle, as reported in the symposium on methods of forceful indoctrination, published by the Group for the Advancement of Psychiatry, these methods produce variable changes in attitudes and behavior, rather than detectable changes in brain function. Furthermore, these changes in attitude and behavior are only transient. In a period of months following his release, the individual subjected to such procedures tends to revert to his former personality. As a general rule, however, the individual's reaction will depend on many factors relating to personality, character, and the immediate situation.

Isolation. The experience of the Navy can be helpful in selecting men for isolated assignments. All personnel assigned to duty in the Antarctic were given a psychiatric interview and a Rorschach test, as a means of evaluating their (1) motivation, (2) past personal effectiveness, (3) ego strength, and (4) interpersonal relationships.

The criteria on which final assessment was based also included peer nominations, performance ratings by supervisors, medical symptoms, and debriefing interviews with those who had completed a tour of duty in the Antarctic. Over a period of 5 years there were no cases of psychotic illness among these personnel; accordingly, it was felt that the program accurately identified and eliminated individuals who might have developed psychiatric illness under the stress of isolation. Recently, "vocational effectiveness" was added to the list of variables which have a bearing on the individual's eligibility for such an assignment.

The human reliability program. Of particular interest for military psychiatry was the development in 1962 of the Air Force Human Reliability Program, which was subsequently adopted by all branches of the Armed Forces. This program is directed toward maintaining a high level of human reliability among those who have access to nuclear weapons. According to pamphlets 160-55 and 35-9, issued by the Department of the Air Force, the presence of the following traits or patterns would contraindicate such an assignment: (1) excessive worry or apprehension concerning nuclear weapons; (2) a record of court martial or unit punishment; (3) overindulgence in alcohol; (4) negligence or delinquency in performance of duty; (5) a prior record of serious or repeated involvement with civil authorities; (6) financial or family irresponsibility; (7) a poor attitude toward duty with nuclear weapons or lack of motivation with regard to the Air Force.

Information is also elicited to facilitate the detection of concealed mental disorders, as characterized by a tendency to be oversuspicious and over-impulsive and by evidence of alterations in the state of consciousness. Among the clues which help to identify the impulse-ridden personality are lack of or immaturity of judgment and glib rationalizations; boredom and irritability or emotional lability; a history of frequent job changes; and passive-aggressive or sociopathic behavior.

Actually, the classic psychoneuroses have been practically nonexistent among military personnel, although conversion reactions occur at times, under conditions of severe stress. Similarly, hebephrenia and catatonic schizophrenia are seen only rarely. Most of the schizophrenic disorders are acute undifferentiated or paranoid. Depressions accompanied by vegetative and physiological changes are quite rare, but manic reactions are encountered occasionally. The prevalent reactions are those characterized by anxiety, "feelings of depression," or personality difficulties.

As mentioned above, the purpose of the Human Reliability Program was to identify and remove unreliable individuals from critical assignments. Unfortunately, to some extent the program has been misused, for it has resulted in the removal of in-

dividuals from the service as unadaptable whereas in reality they are unadaptable only insofar as a highly critical assignment is concerned. Once again, it should be pointed out that today selection for military service must exceed the proportion of 300 out of 32,000 men who fulfilled the rigid requirements of the Lord and Gideon.

Space medicine. The advent of the atomic bomb and the era of space flight have brought with them new problems of individual and group adjustment, many of which are still unknown. The psychophysiological aspects of space flight require consideration of problems of prolonged weightlessness, eating and breathing conditions aboard spacecraft, psychological stability in a completely alien environment, the effect of variations in gravity, the effect of changes in circadian rhythms, the problems of sensory deprivation and sensory overloading, cosmic radiation, and the neuroendocrine aspects of stress, as described in Selye's general adaptation syndrome.

The selection of suitable astronauts raises other problems. The psychiatric aspects of this phase of selection have been described by Flinn:

During the 1920's a clinical psychiatric interview was introduced in the Air Corps as part of the pilot selection procedure, and it has continued in use, with modifications and refinements, until the present. Despite widely held doubts concerning its validity, no more objective substitute has yet appeared which seems able to assess complex personality characteristics such as motivation, attitudes, flexibility, maturity, and level of adjustment The current USAF selection battery predicts success or failure in primary flight training with a high level of accuracy. However, long-term adaptability to flying depends not only upon technical aptitude, but also upon complex factors such as basic emotional stability, motivation, and chance experiences in the life of the individual. Objective testing aimed at measuring predisposition to maladaptive responses to the stresses of military flying have shown some promise, but it is doubtful if a level of accuracy comparable to that achieved in aptitude testing can ever be expected. At present there is no substitute for the clinical psychiatric or psychological evaluation in judging over-all adaptability.

While it is possible that some of the stresses of space flight have been overestimated, methods to reduce this stress have been studied extensively. Thus, consideration has been given to the utilization of such esoteric methods as hypnosis, conditioning by yoga exercises, the use of psychic energizers, hypothermia, prolonged sleep or hibernation, and the introduction of substitute homeostatic mechanisms by both chemical and electronic means.

A Unified Concept of Preventive Psychiatry

As mentioned elsewhere in this volume, with respect to most psychiatric disorders, no specific etiological agent has been identified and universally accepted to date. Rather, it is generally felt that these disorders are multicausal in origin. It follows, then, that preventive measures may be reasonably directed at diverse points or levels of the unstable system which produces psychiatric disorder.

In the military community, primary prevention has focused on maintaining a balance between environmental stresses and emotional supports, utilizing the military criteria of ineffectiveness described earlier as measures of the success or failure of preventive efforts. Secondary and tertiary prevention have been accomplished by providing a continuum of psychiatric care, employing all available modalities of treatment and rehabilitative techniques.

Howe has defined a "community" as that dimension of human interaction (existing on a symbolic level) which is characterized by a sense of common destiny. Thus a community may be a geographic area, an industry, a social institution, a professional group, or, in fact, any discrete group of human beings which can be viewed collectively as distinct from other groups of human beings. The health or ineffectiveness of such a group might be measured by such yardsticks as rates for marriage, divorce, birth, suicide, accident, delinquency, addiction, unemployment, absenteeism, "dropouts," morbidity, production indices, etc. The specific stresses to which such a group is subjected may be peculiar to specific stages of psychosexual development, as suggested by Erikson; they may arise from a deficiency of the environmental supplies listed by Maslow and Caplan. And they may stem from factors which emerge clearly in connection with military life, e.g., intergroup tensions, economic factors, disciplinary controls, the quality of public and other leadership, group identification, religious practices, ideals and ethics, inadequate mental health education, and a lack of incentive and motivation.

Suggested Cross References

For further discussions of primary, secondary, and tertiary prevention in psychiatry see Sections 46.1, 46.2, and 46.3, respectively, in Area I, on community psy-

chiatry. Also, see Section 28.1 for a detailed discussion of the gross stress reactions and Section 28.2 for information regarding traumatic war neurosis.

Chapter 50

Occupational (Industrial) Psychiatry

50.1 • • •

W. DONALD ROSS, M.D.

Definition

By definition, the term "industrial psychiatry" refers to certain elements within the broader framework of occupational psychiatry, and, as such, it may well become obsolete eventually. In the meantime, however, it has been retained in the interests of conceptual clarity: for example, there is a tendency to confuse occupational psychiatry with occupational therapy, despite the fact that these concepts are entirely unrelated. Obviously, the use of the word "industrial" (rather than "occupational") would serve to eliminate this source of confusion. Yet, although it offers certain semantic advantages, the use of the term "industrial psychiatry" in this context, i.e., as a substitute for occupational psychiatry, is clearly inaccurate. The field of occupational psychiatry extends well beyond those occupations and work settings which would be labeled "industrial"; it encompasses business, agriculture, government, hospitals, and similar institutions. On the other hand, occupational psychiatry is not concerned with military life; nor do its principles apply in the classroom. The unique aspects of military psychiatry and educational psychiatry warrant their status as separate subspecialties.

Historically, occupational psychiatry antedated community psychiatry; actually, it represents another side of the same coin. More specifically, community psychiatry addresses itself to the mental health needs of individuals within a prescribed geographic area; occupational psychiatry, in turn, focuses on the mental health needs of individuals within a specific functional area. The adult's functional area is his office, or the factory or field in which he works, and where he spends more than half his waking hours. The functional area is not the exclusive province of occupational psychiatry, of course; it is also the concern of environmental medicine which subsumes occupational or industrial medicine. The

occupational psychiatrist must work closely with other occupational physicians and hygienists, and with personnel workers who bear the responsibility for either job assignments or management-labor relations.

Patterns of Practice

The occupational psychiatrist does not treat mental disorders which are not directly related to the patient's occupation. Thus, while he will focus on the early diagnosis of such disorders as part of his diagnostic assessment, he must discriminate between the role of occupational and nonoccupational factors in precipitating and maintaining the patient's illness. In any event, the occupational psychiatrist is rarely involved, directly or indirectly, in the treatment of this patient population, even when the crucial role of occupational factors has been clearly established. Rather, he uses the findings derived from various diagnostic techniques primarily for teaching purposes. The scope and nature of the occupational psychiatrist's teaching activities are described in further detail below. In general, once the occupational psychiatrist gains sufficient insight into the psychodynamics of a single "patient," or a group of "patients," he is expected to share this knowledge with his medical and administrative colleagues. Hopefully, these personnel will then modify their relationships with their co-workers to reflect this newly acquired psychological understanding. The occupational psychiatrist may also use diagnostic findings to support his recommendations that various preventive measures be implemented within the occupational environment. And, finally, these diagnostic findings are an important source of information when patients must be referred to other physicians and psychiatrists for treatment or to health or welfare agencies in the community.

In light of their limited therapeutic function, it is not surprising to find that occupational psychiatrists are rarely employed on a full time basis. The great majority serve, for a few hours each week, as consultants to the medical department of an industrial or business corporation, or a nonprofit organization. The

advantages of this pattern are self-evident. Certainly, a full time occupational psychiatrist could devote more attention to the preventive aspects of the field. To date, however, psychiatrists have primarily demonstrated their reluctance to give up private practice completely. And, in fact, this pattern has other, equally important advantages. Financial independence, or, more accurately, the fact that the psychiatrist need not depend on a single employer for his livelihood, ensures his professional objectivity. The occupational psychiatrist is then better prepared to accept the fact that the corporation (and its management) as well as its employees may be the patient, and to deal with both appropriately.

The Functions of the Occupational Psychiatrist

Consultation and teaching. Caplan has pointed out that attempts on the part of psychiatrists to monopolize community mental health programs may have unfavorable repercussions. He has suggested that psychiatrists concentrate instead on those activities in which they can utilize their unique skills to their advantage. In the occupational setting, the psychiatrist can function most effectively as a consultant whose services are available to occupational physicians and nurses, corporation executives, personnel executives, foremen, supervisors, union stewards, and union executives.

In his role as consultant, the psychiatrist will have ample opportunity for didactic teaching, and his efforts in this connection may serve to promote understanding of personality and behavior dynamics among the laymen and nonpsychiatrist physicians with whom he comes into contact. In fact, however, the most effective teaching is rarely formally labeled as such. More specifically, those personnel (professional and nonprofessional alike) who meet with the psychiatrist to discuss an individual employee who presents a psychiatric problem will be most responsive to his efforts and best able to absorb—and apply—the “teachings.” This does not mean that didactic teaching, through group discussion, for example, can have no useful purpose; on the contrary, the group discussion method represents a legitimate educational technique. Nevertheless, the use of this method carries with it certain pitfalls which merit careful consideration. Usually, the goals of these discussion groups are not defined with sufficient clarity. As a result, group teaching soon gives way to group psychotherapy, or, at best, the discussion group represents an admixture of both procedures. Quite apart from the fact that neither procedure can be successfully implemented under such circumstances, group psychotherapy in this setting may have serious adverse effects. Presumably, these individuals have been assembled for educational purposes. The leader of such a group need not possess specific therapeutic skills; nor would he be expected to possess prior

knowledge of the psychiatric status of individual group members. On the other hand, however, these deficiencies represent a serious handicap in a leader who may have to deal with a group of captive patients.

The prevention of mental illness due to occupational factors

Primary prevention. In his role as consultant, the occupational psychiatrist learns at first hand of those factors in the working environment which contribute to maladjustment and emotional illness. At the same time, the psychiatrist is aware, of course, that employees and executives alike may rationalize their failures in other areas of life by attributing them to unfavorable working conditions. Nevertheless, the psychiatrist can use such information, while safeguarding the confidentiality of the individual, as the basis for recommendations which pertain to groups of persons. Typically, these recommendations will refer to methods of leadership and supervision or to working conditions, including those specified in union-management contracts.

Secondary prevention. Information available in the personnel and medical departments, on employee absenteeism, accidents, inefficiency, interpersonal friction, garnishments, and the frequency of visits to the medical dispensary, facilitates early case finding. However, a recent study, conducted by a Cincinnati industrial mental health team must be cited in this connection. Specifically, these workers found early case finding was more effective, that is, employees were more strongly motivated to seek further medical or psychiatric help or to enlist the help of social agencies, when such referrals were arranged by physicians or personnel executives in their own plant. On the other hand, they were less likely to follow through on recommendations made by psychiatrists who had been called in from outside to investigate the causes of job disruption if the indigenous professionals or semiprofessionals were not participating in the referral process.

Tertiary prevention. Occupational psychiatrists seek to prevent chronic invalidism by emphasizing the rehabilitation of those employees who have been unable to work for prolonged periods of time because of mental or emotional illness. It should be mentioned here that most business corporations are quite willing to rehire employees, especially if a psychiatrist who is familiar with the working environment is able to attest to the employee's readiness to return to work; this usually successfully dispels any existing doubts. Inevitably, however, some ex-patients will be denied access to their former place of employment. In such cases, sheltered workshops and halfway houses, which are described elsewhere in this volume, are of particular value.

Finally, the efforts of the occupational psychiatrist

in the area of tertiary prevention will also apply to those employees who have suffered some disability as a result of an occupational injury or disease, and for whom this disability provides important secondary gains. The psychodynamics of this reaction are discussed in detail below.

Clinical Aspects of Occupational Psychiatry

“Occupational syndromes.” Syndromes which are commonly attributed to occupational factors, such as writer’s cramp or miner’s nystagmus often turn out to originate from other causes, although they may include some occupational components: for example, a disability pension may provide secondary gains. On the other hand, attention to certain symptoms which are most likely to appear first in the occupational setting, (e.g., absenteeism, accident syndrome, moonlighting, neurocirculatory asthenia, problem drinking, retirement concerns, and traumatic neurosis) may prevent more serious disability.

Secondary sequelae. “Compensation neurosis” refers to the tendency to maintain those symptoms which arose in the occupational setting originally, as a defense against losing the secondary gains derived from disability “benefits” or hospitalization. The diagnostic label in such cases should reflect the patient’s underlying neurosis or personality disorder, regardless of the precipitating factors. However, if they are to be effective, plans for the patient’s treatment and rehabilitation must take such factors as secondary gains and the precipitating role of the occupational setting into consideration. For prognostic purposes, it is useful to classify such patients as “has beens” or “never wases.” Those patients who had a prior history of responsible adjustment to work and family life, before they regressed to a state of dependency, have a better prognosis with individual or group psychotherapy. The prospects are much less favorable for those patients whose previous life pattern suggests that their occupational accident or illness was just another incident in a downhill course. Both groups of patients typically demonstrate a strong tendency to rationalize, on a conscious or unconscious level. It is important, therefore, that the diagnostic assessment reflects information solicited from other family members or from the patient’s co-workers and supervisors in his previous working environment.

Clinically, a history of recurrent catastrophic dreams and other features of traumatic anxiety following an occupational injury are considered indicative of the regression or ego distortion which accompanies a true traumatic neurosis. The secondary gains provided by compensation then serve to maintain the neurosis. It has been hypothesized that neuroses maintained by secondary gains have their etiological roots in the fact that compensation pay-

ments, pensions, or reduced responsibilities gratify dependent or aggressive impulses. It follows, then, that tertiary prevention in this type of disability will be most effective if legal action is taken to provide the patient with funds only to cover treatment and rehabilitation; clearly, to provide continuing financial support outside of a treatment plan would not be in the patient’s best interests.

Primary and secondary prevention in the occupational setting require prompt intervention when psychiatric manifestations follow accidental injuries and exposure to occupational health hazards. A traumatic neurosis following an overwhelming threat and accompanied by typical features of traumatic anxiety should be diagnosed as a gross stress reaction and treated before prolonged regression and ego distortion have occurred and have been reinforced by secondary gains. Toxic disorders involving the skin or nervous system which were due to an industrial environmental agent originally may follow a similar pattern; that is, such disorders can be maintained by psychophysiological factors induced by changed life circumstances, which would include the inactivity made possible by a disability pension.

Research in Occupational Psychiatry

Occupational settings which provide detailed records on a relatively nonshifting population under fairly close observation provide a fertile field for research. To date, however, this field has been tilled more extensively by social scientists than psychiatrists.

Chapter 51

Clinical Psychology

51.1 • • •

FRED BROWN, Ph.D.

History

Clinical psychology is one of the newest of the mental health specialties, but in point of time its accelerated growth and proliferation have established it as a significant component in all planned or operating mental health programs. The first psychological clinic was established in 1896 at the University of Pennsylvania by Lightner Witmer and grew out of the then current interest in individual differences that had already been stimulated by McKeen Cattell's work in psychometrics begun in 1886. Guy Whipple's *Manual of Mental and Physical Tests* appeared in 1910, and in 1911 the Goddard revision of the Binet-Simon intelligence test made its appearance in America, to be superseded by Louis M. Terman's Stanford Revision in 1916. These beginnings, motivated by the urge to objectify psychology by emphasizing measurement of mental processes and thus to sever all bonds with its subjectivist-philosophical antecedents, were oriented more toward research than toward what are now known as service functions.

In 1918, R. S. Woodworth developed his "Personal Data Sheet" for screening potential military psychiatric casualties, and this instrument, the grandfather of all personality inventories, was later used in civilian clinics. The Rorschach method, which now dominates the field of projective techniques, was created in 1921 and spurred the development of the projective approach to personality analysis and evaluation. Finally, the demands for psychological personnel and techniques in two world wars focused attention on the contributions of the clinical psychologist to the expanding field of mental health, brought him into close contact with psychiatrists and other medical personnel, and established him as a member of the mental health team. The significance of the functions and roles of the clinical psychologist has broadened and deepened as a consequence of the Joint Commission Report,

Action for Mental Health, and the growing emphasis on comprehensive community mental health programs.

Scope

The 1963 Directory of the American Psychological Association lists 2,899 clinical psychologists of which number 1,300 are diplomates of the American Board of Examiners in Professional Psychology. Not all clinical psychologists are accounted for in this figure, a fact evident in the results of the National Scientific Register survey of psychologists conducted in 1962, which revealed that of 9,348 questionnaires returned by psychologists, 3,441 identified themselves as clinical psychologists. George Albee reported to the Joint Commission on Mental Illness and Health that there are more than 18,000 psychologists in the American Psychological Association, with only one third of that number engaging in clinical services involving the mentally ill. Albee's estimate of approximately 6,000 psychologists in the United States who constitute a pool of mental health workers would probably be increased to 7,830 if the total 1965 roster of 23,500 fellows, members, and associates of the American Psychological Association is taken into account and if all persons in clinical, counseling, school, educational, and personality psychology are included.

There is considerable overlapping of interests and functions among these subfields. Individual diagnosis and therapy are major specialties of the clinical and school psychologists and supplementary ones for counseling and personality psychologists. Other areas of overlap include educational counseling and measurement, school and personal adjustment, management of behavior problems, vocational counseling, and utilization of objective tests. Only clinical psychologists make extensive use of projective techniques.

At present, clinical psychologists play an important role as psychodiagnosticians, therapists, teachers, and research workers in the psychiatric units of general hospitals, community and private mental health clinics, medical schools, and social agencies. Although there has been a slow increase in the number of training facilities for clinical psychologists, professional progress is uneven because of conflicts with psychia-

trists over role and function autonomy, a lack of uniformity in training content and objectives, and unremitting struggles of this relatively new profession to define itself. As a consequence of these and other factors, training and competence levels among clinical psychologists in the areas of psychodiagnostics and therapy vary considerably and have aroused continuing concern on the part of responsible leaders in the field who are devoting themselves to the task of improving education and training. A very important aspect of the American Psychological Association's work in this area is the activities of its Education and Training Board and the Committee on Evaluation concerning approval of doctoral programs in clinical psychology and counseling psychology and of internships for doctoral training in clinical psychology. These activities are supplemented by state and regional psychological associations that concern themselves with the improvement of training and service by establishing licensure and certification standards.

Activities of Clinical Psychologists

Research. This is undoubtedly the most important general contribution of the psychologist and the most valuable one offered to psychiatry by the clinical psychologist. In commenting on William F. Soskin's study for the Joint Commission, *Research Resources in Mental Health*, the Joint Commission Report stated:

Currently, the major share of systematic investigation on mental health programs is being conducted by psychologists. Dr. Soskin reports that over 50 per cent of all N.I.M.H. grants go to investigators from this discipline. . . . While many of the fundamental concepts and hypotheses of modern psychiatry derive originally from clinical observations and from *what now appear to have been* poorly designed studies, emphasis today is placed increasingly on sophisticated research designs, on highly specialized research techniques and instruments, and on complex statistical procedures for data analysis. Psychologists are likely to have had the requisite training and experience for this type of research and this fact helps to account for their prominent position in this field.

Psychologists contribute theoretical and experimental papers to over 20 basic psychological journals in addition to psychiatric and other journals. A few of the areas covered by this spate of research activity include psychopharmacology, developmental problems, geriatrics, test construction and validation, personality diagnosis and adjustment, psychoanalytic theory, therapeutic processes, brain damage and mental retardation, behavior and habit problems, psychosis, psychoneurosis, psychosomatics, mental health and rehabilitation, and marriage and family problems. The psychologist's special training and competence in the research area make him a valuable consultant and co-worker in hospitals, clinics, and other agencies engaged in mental health research. A good source of condensed information regarding psychological research relevant to the interests of

psychiatrists is *Psychological Abstracts*, a monthly publication of the American Psychological Association.

Psychodiagnosis. The clinical psychologist in his psychodiagnostic role uses a battery of appropriate tests and measures, both projective and objective, for the purpose of clarifying the dimensions of the patient's illness. Depending on the reason for referral and the nature of the particular case, a competent clinician can, through the use of such tests, appraise a patient's ego strength, the degree and nature of underlying malignant processes, and his capacity for change.

Very often, covert malignant psychopathological potentialities are not detected in the ordinary psychiatric examination but come into focus through the psychological examination. It may be possible to evaluate the patient's type and mode of thinking; the type and psychoeconomics of his defenses, whether entrenched or resilient; the quality of his affect vis-à-vis object relations; and the diagnostic picture, for example, depression, schizoaffective reaction, psychotic decompensation, or anxiety state. The psychological examination may contribute data useful for the differential diagnosis of organic brain syndromes, neurotic disturbances, and psychotic reactions. The psychodiagnostic test battery has proved useful in delineating focal conflicts that may not have been seen in total perspective in the clinical situation. Psychodiagnostic tests aid also in formulating a therapeutic plan, evaluating the progress and outcome of therapy in longitudinal appraisals, and contributing to an understanding of the patient's reaction to shock, pharmacotherapy, and other therapeutic modalities.

Although it is not imperative that every patient seen by the psychiatrist be referred for psychological evaluation, a comprehensive psychodiagnostic assessment of the patient's resources and liabilities prior to initiation of treatment can, in many instances, prove valuable in helping determine therapeutic approach.

Psychotherapy. This is the most controversial area involving both the clinical psychologist and the psychiatrist. In an early Group for the Advancement of Psychiatry report, the statement was made that psychiatrists should continue to refer some patients to clinical psychologists for such special treatments as vocational guidance, remedial reading, retraining procedures, speech training, and psychotherapy. In addition, it was stated that the type of psychotherapy performed by the clinician is conditioned by his training and competence, by the type of patient, and by the circumstances under which treatment is conducted. It was emphasized that the clinical psychologist must work in close association with the psychiatrist, since independent operation by the clinical psychologist may incur diagnostic error or result in either the failure to detect and treat the

early stages of serious psychiatric conditions or the failure to recognize some physical disorder that may be the basis for the maladjustment. The Joint Commission Report of 1961 pointed out:

A narrow enforcement of psychiatric conviction that 'nobody should do psychotherapy except psychiatrists' would effectively deny its benefits to patients now receiving it from non-medical therapists with or without supervision of psychiatrists. Such enforcement would also raise questions regarding the psychotherapeutic nature of other interactions of patient and therapist carried out in the name of 'group therapy,' 'drama therapy,' and so on.

Conversely, however, to deny the patient access to a doctor trained in medicine opens up the possibility that a physiological, as opposed to a psychological or social, basis for the illness may be overlooked—unless the psychotherapist has access to and uses medical consultation.

Recognizing the acute shortage of mental health workers and noting that criteria of competence apply equally to psychiatrists and psychologists, the commission recommended the practice of psychoanalysis by professional psychoanalysts and any other professionals who, although lacking a medical education, possess aptitude for and competence and training in techniques of psychotherapy. The commission further recommended that nonmedical mental health workers with such qualifications be allowed to perform short term psychotherapy "by objective, permissive, nondirective techniques." The report by the commission emphasized that such treatment should be carried on "within the framework of their hospitals and other professional service agencies" and "in all cases should be undertaken under the auspices of recognized mental health agencies."

In reaction, clinical psychologists have taken a more aggressive view in defense of their professional autonomy, rejecting in principle and often in practice the concept of medical supervision. In pursuit of professional independence, many clinicians are establishing their own training centers and clinics. Although some psychologists are not enthusiastic about the prominence given psychotherapy by their clinical colleagues and feel that this may diminish research motivation by overemphasizing the practitioner role, others concur with this relatively new activity. Shakow has said with regard to psychotherapy that particular professional identification need not necessarily be involved, particularly in areas concerned with human psychology and motivation. He further questioned whether, in certain circumstances, conventional medical training may not hinder rather than aid in preparation for psychotherapy. Some clinical psychologists opposed to the perpetuation of current medical and disease-oriented conceptions of pathological processes have rallied to the view of Szasz that the concept of mental illness is "a logically highly dubious proposition." This view is strongly advocated by George Albee, who stated:

The plain fact is that nearly all of the people seen in psychologists' offices or on the wards of 'mental hospitals' are *not* sick. While the concept of mental illness had a sort of temporary usefulness in counteracting the older explanations of sinfulness and taint, it is now a millstone around our neck.

This intemperate statement represents an extremist view, which is the more significant when propounded by an acknowledged leader in the field.

More cautious opinions, however, suggest a more conservative view and emphasize the need for upgrading the quality of work being done by private practitioners in the field. It should be noted that in 1961 less than 5 per cent of clinical psychologists were in full time private practice.

In considering the relation of the clinical psychologist to psychotherapy, the crucial, interprofessional issue is whether the clinician is competent to treat psychiatric patients in private practice and, above and beyond professional rivalries, what is best for the patient. Apart from situational difficulties, mild character disturbances, and those conditions listed by the Joint Commission report as capable of being treated by the competent psychologist in his office, close collaboration between psychologists and competent psychiatrists would be in the best interest of the patient, regardless of the particular setting in which therapy is conducted. Direct psychiatric supervision of psychologists engaged in psychotherapy should be provided as a service in relation to the needs of the psychologist and his patient rather than as an inflexible institutional policy.

Although a conscientious psychologist is generally very discriminating in the choice of patients he accepts for treatment, in his private practice with mentally ill persons he is unable to avail himself of anti-psychotic medication and other psychochemical agents, to the serious detriment of those patients for whom such medication is indicated. This is especially significant in view of the expanded use of this therapeutic modality by psychiatrists. The clinical psychologist lacks hospitalization privileges, cannot shift to electroconvulsive therapy if this is indicated, and thus lacks the resources available to the psychiatrist for continuing diagnosis and treatment. In addition, he is not trained in the diagnosis and management of psychophysiological reactions. The psychiatrist is a member of a profession that has within itself all the necessary therapeutic modalities. He can prescribe what is best for the patient, whereas the psychologist, when such modalities are required—and one hopes for the patient's sake that recognition of such a need is forthcoming and not belated—must send the patient to members of another profession.

Full and realistic recognition must be given to the clinical psychologist's contribution as a therapist in the collaborative setting of institutions and agencies, where his experience as therapist and psychodiagnos-

tician deepens his understanding of psychodynamics and psychopathology and increases his worth as a teacher in a variety of training programs. However, the role of the clinical psychologist as an independent colleague and as a member of a team where he carries primarily psychodiagnostic and research responsibilities is more clearly defined and less subject, at present, to inherent professional restrictions than is true of his role as a practitioner of psychotherapy, private or otherwise.

Suggested Cross References

For further discussions of the clinical psychologist's contribution to psychiatric assessment and for more complete descriptions of the tests mentioned in this section, see Sections 12.1, 12.2, and 39.3, which deal, respectively, with tests of personality and intelligence, tests useful for the assessment of organic brain damage, and tests employed for the evaluation of children. For an example of clinical psychology research that has direct relevance to psychiatry, see Cattell's Section 9.1 on personality theory derived from quantitative studies. Sections 34.2 and 34.3 describe therapeutic techniques, behavioral therapy, and nondirective therapy that derive from psychology.

Chapter 52

Psychiatric Social Work

52.1 • • •

C. KNIGHT ALDRICH, M.D.

Although the profession of social work is relatively new, it has become in many ways the profession outside medicine that is most closely allied with psychiatry. Social workers who are employed in psychiatric hospitals or clinics traditionally have been called psychiatric social workers, but even those who are employed in other capacities encounter problems that have much in common with psychiatry.

History

Social work evolved out of the private dispensing of charity. Early charitable organizations required simple differentiation of the deserving or unfortunate poor from the undeserving or indolent poor. During the late 19th century, the validity of this arbitrary and moralistic system of differentiation came to be questioned; attributing poverty and its associated troubles either to inborn moral weakness or to simple bad luck was no longer considered an adequate basis for its understanding. The explanations for these problems were next sought in society's failure to provide the means of avoiding misfortune or of coping with misfortune, and so the first more sophisticated efforts to counteract social problems emphasized social welfare. A primary concern with the effect of the immediate social environment on human suffering, therefore, characterized the therapeutic approach of the social workers who, around 1905, were recruited for the first time to work with patients in medical settings.

One of these settings was the Massachusetts General Hospital, where, under the guidance of Richard Cabot and J. J. Putnam, a clinic was established in which psychoneurotic patients were treated by social workers. At about the same time, social workers began to be employed in Boston, Chicago, and Baltimore in institutes for the study and care of disturbed children. The third setting was the Manhattan State

Hospital, where, inspired by Adolf Meyer and his wife, a social worker was employed as an after-care agent to help discharged psychiatric patients resume their responsibilities in the community and, indirectly, to reduce the financial burden of such persons on charities.

The worker's appraisal of a client's social problem depends on accurate communication, and the significance of interviewing as the social worker's main technique for understanding the impact of social forces on the individual was underscored by Richmond in 1917 in her book, *Social Diagnosis*. In this book, which had perhaps more influence on the development of social work than any other document written by a social worker, Richmond recognized not only the importance of social pressures but also the importance of interpersonal relationships in the genesis of social problems. At about the same time, the contributions of Freud and other psychoanalysts began to provide a framework for understanding interpersonal relationships, and much psychoanalytic theory has consequently become integrated into the training of psychiatric social workers.

Beginning in the 1920's, many psychiatric social workers found employment in child guidance clinics. Initially, they worked exclusively with parents, in close collaboration with child psychiatrists, who treated the children. In recent years, the roles of the two professions have become less rigid, and now social workers are often directly involved in the treatment of children. The early collaborative experience in the children's field proved so satisfactory for both the psychiatrist and the social worker that a similar collaboration has been extended to the adult field, particularly in out-patient clinics. Another example of this collaboration is evident in the development of interdisciplinary research, to which the social worker has made substantial contributions in family and follow-up studies.

Education and Training

Collaboration between psychiatrists and social workers extends to the area of training. Psychiatrists teach in most schools of social work; and, conversely,

in many medical schools and training centers, psychiatric social workers participate actively in the teaching of medical students and psychiatric residents.

Although the direct influence of psychoanalysis in social work training was at first restricted for the most part to special sequences for psychiatric social workers, the relevance of psychoanalytic theory in preparation for casework in family agencies and in other settings soon became apparent. With this recognition and with analogous developments in related fields, the policy in social work schools of requiring individualized course sequences in preparation for employment in medical, welfare, and other settings has been replaced by a policy of requiring the same basic or generic program for all social workers. This program in American schools ordinarily lasts 2 years, leads to a master's degree, and consists of didactic courses and field work.

The didactic sequence includes basic courses in human behavior, personality development, and psychopathology, in which psychiatrists often share teaching responsibility. These courses are balanced by courses in the family and the community, as well as by instruction in social organization, welfare, and reform; in all these courses, social scientists participate.

Although the didactic training of all social workers is approximately the same and includes information about the whole range of social work settings, each student's field work—supervised practice that corresponds roughly to the clerkships or externships of the medical student—is usually restricted to two settings: social agencies or hospitals and clinics. The types of field work placement that are selected by and for the student reflect his specific interests and capabilities.

Throughout training and practice, the work of the social worker is carefully supervised by senior workers, with consultation from psychiatrists and others when needed. The social work tradition of supervision and consultation thus provides assurance of a high standard of competence.

The supply of professionally trained social workers does not come close to meeting the current demand in the United States. In 1965, considerably fewer than half of the more than 100,000 social workers were fully qualified by training; and a job description of social worker was by no means a guarantee that the person was capable of high quality professional service. The proportion of trained workers in psychiatric settings is considerably higher than in other areas, but the number of open positions is increasing at a rate faster than the increase in trained candidates.

Methods of Social Work

There are three major social work methods: casework, which has been by far the most commonly

used; group work; and community organization. Interviewing skill is needed in all three methods; in fact, casework relies primarily on interviewing for both assessment and therapy.

The goal of casework therapy is the maintenance or modification of the client's adaptive patterns. The goal is achieved by various ego-supportive measures that have a great deal in common with the measures used in supportive psychotherapy. By both training and experience, the caseworker is usually better equipped than most psychotherapists for the individualized application of environmental modification and the use of community resources and concrete services to supplement treatment by interview. On the other hand, he is not so well equipped as the psychoanalyst in the understanding of the unconscious. Nevertheless, for many cases there seem to be few technical differences between the casework practiced by the well trained social worker and the supportive psychotherapy practiced by the dynamically oriented psychiatrist.

In group work the social worker deals with groups of patients or with relatives of the mentally ill. In hospitals, groups are established with various purposes in mind: to provide orientation to the hospital and treatment, to aid in active treatment of patients, to facilitate discharge planning, to provide transitional and after-care assistance. Most group workers, however, practice outside of hospitals, usually with a primary focus on youth in community centers and settlement houses.

Community organization as a social work method is concerned with the administration, planning, and development, as well as with the organization, of the whole spectrum of the community's efforts to meet social needs.

Scope of Social Work

In many psychiatric clinics, the social worker makes a substantial contribution to diagnosis. He obtains background information from the prospective patient, appraises the social situation, and enlists the help of family members, significant relatives, and other informants, such as physicians and clergy, in overcoming the patient's unrealistic or exaggerated fears of psychiatric care. To a somewhat lesser extent, the social worker prepares patients for hospitalization.

In the psychiatric hospital, the social worker's major function is casework with members of the patient's family, beginning with an interpretation of the nature of the hospital or other facility, of the details of psychiatric treatment, and of the patient's prognosis. Throughout the patient's hospitalization, the worker continues to maintain contact with the family, carrying out casework as indicated, with particular concern for their potential contributions to the patient's easy transition from hospital to home. Casework may also be carried out with hospital pa-

tients, usually with emphasis on their eventual return to the family and to the community. In some psychiatric hospitals certain social work functions are carried out by group workers.

Casework is almost always indicated in rehabilitation, as in establishing liaison with potential employers or in finding and arranging for foster homes when family care is appropriate. Casework is extensively used in after-care clinics for the treatment of discharged mental hospital patients and in psychiatric out-patient clinics for the treatment of both the patient and his relatives.

For many psychiatric patients, alternatives either to hospitalization or to psychiatric clinic care may be considered at the time of intake, and other community resources may be helpful to the families of psychiatric patients. The social worker's knowledge of community resources can also help in providing temporary delaying actions until a patient is prepared for psychiatric care. Some of the community resources administered by social workers include: (1) public assistance or public welfare agencies administering direct relief, aid to families with dependent children, old age assistance, etc.; (2) family agencies, which traditionally focus on marital problems and problems of child care or child management; (3) agencies devoted primarily to child welfare, with concern for the protection of dependent children, for adoption, or for providing children with foster home care or residential treatment; and (4) homemaker agencies, often closely associated with child welfare agencies, which provide supervised home assistants to preserve the integrity of homes where the mother of young or adolescent children is absent or disabled or where aged or physically ill patients are unable to carry out homemaking functions.

Social work is also extensively carried out in agencies not administered by social workers, including: (1) medical settings such as hospitals, rehabilitation and public health agencies, and visiting nurse associations; (2) schools in which, beginning in 1907, visiting teachers carried out social work activities (in

many communities, professionally trained school social workers have now replaced visiting teachers); and (3) correctional institutions such as family and juvenile courts, the psychiatric clinics of other types of courts, and probation offices.

Future Trends

In recent years, social work education has focused somewhat more on the social sciences and proportionately less on psychiatry. At the same time, it has concentrated more on functions and agencies uniquely identified specifically with social work. It is not likely, however, that the collaboration in practice between social work and psychiatry will substantially diminish. Instead, particularly as the demand for out-patient care of emotional problems increases and as greater emphasis is placed on comprehensive patient care, the professional collaboration between psychiatrists and social workers is likely to increase and expand.

Chapter 53

Psychiatric Nursing

53.1 • • •

HILDEGARD PEPLAU, R.N., Ed.D.

History

Nurses have been employed in psychiatric settings for less than a century. It was at McClean Hospital in 1882, 10 years after the opening in America of nurse training schools, that nurses began to develop a role in psychiatric facilities. The greatest impetus to this development came with the passage of the Mental Health Act in 1946. Funds were then provided to enable professional nurses to develop psychiatric nursing as a major area of specialization.

The question of such specialization had been raised by a nurse as early as 1900. But the profession of nursing could not economically support pursuit of this idea, which today is recognized as the main source for continuously revitalizing both nursing services to psychiatric patients and basic nursing educational programs. Instead, nursing staked its claim first on the proposition that all registered nurses should be prepared for the sociopsychiatric aspects of all illness as part of their role as staff nurses. Accordingly, exposure to dominant psychiatric theories and to practices in psychiatric settings was established by 1917. Today all basic schools of nursing allocate a portion of the student experience to study and practical experience with psychiatric patients. In the last decade, with more rapid development of clinical specialization in psychiatric nursing and more widespread public interest in and support of psychiatric education and services, professional nurses have been enlarging and strengthening the scope of nursing practices in psychiatric settings.

Types of Nurses

In discussing the role of nursing in psychiatric services, one must make a clear distinction between registered nurses and psychiatric nurses. Differences in their educational qualifications lead to differences in

personal development and scope of professional competence.

Registered nurses. There are currently 850,000 registered nurses in the United States, of whom about 600,000 are actively employed. Of these, approximately 18,500 are employed in psychiatric settings: about 75 per cent are employed in public mental hospitals, 8 per cent in private hospitals, 10 per cent in institutions for the mentally retarded, and 766 nurses in out-patient psychiatric clinics. Additionally, nurses who work in such situations as public health agencies, industry, schools, and general hospitals are also concerned with early case finding, management of sociopsychiatric nursing problems brought to their attention, and follow-up nursing services to discharged psychiatric patients.

Psychiatric training. Recent reports indicate that nurses employed in mental health establishments, as a group, have substantially higher levels of education than other employed professional nurses. Three fourths of such nurses have a 3-year diploma or Associate in Arts degree; 20 per cent a baccalaureate degree; and 4 per cent a graduate degree.

The specific psychiatric preparation that nurses bring to their work varies. In all schools of nursing it is generally accepted that the total educational experience contributes to the individual's work as a staff nurse in general and in psychiatric hospitals. With only rare exceptions, this total experience includes a basic educational experience in theories and practices relating specifically to nursing of psychiatric patients.

Hospital schools of nursing usually have a 3-year program of study leading to a diploma in nursing. The psychiatric portion of the total program usually consists of 8 to 16 weeks of affiliation with a public mental hospital. Recently, many hospital schools have started to consider the feasibility of using psychiatric units in general hospitals for this purpose.

An affiliation program is generally conducted by nurse instructors employed by the hospital, though in some instances the school of nursing may provide the teachers. Often, there is a ratio of one teacher to 30 to 100 students. The students frequently come

from several diploma programs on a rotating basis for the period of study and usually live in a residence provided by the hospital. The content of the affiliation program typically includes rotation of the student through acute, intensive treatment and chronic male and female wards, although recently there is a tendency to concentrate the student's experience in just two wards. Classes in which psychiatric entities and explanatory theories are presented are conducted by nurses, hospital psychiatrists, and others. Traditionally, each student nurse completes a case study; recently, nurse-patient interaction studies have been undertaken together with seminars and readings designed to increase the student's understanding of her relationship with one patient. Students also participate in such available meetings as diagnostic and discharge staff meetings and ward team or ward government. Visits to occupational therapy, social work, and clinical psychology departments are designed to help the student see interrelationships between these disciplines and the role of staff nurse in that setting.

Affiliation programs have failed to capture the interest of student nurses and recruit them for work in psychiatric settings. Since 83 per cent of all nurses graduate from hospital schools of nursing, it would seem that the in-residence educational experience provided by the hospital would also serve as a major recruitment device. That this has not occurred cannot be explained simply. After graduation, the young nurse is eager to work in a viable center where there are enough qualified doctors and where recoveries are readily visible. In public mental hospitals, the work is fraught with shortages of all kinds—personnel, equipment, and know-how. Lack of adequate professional nurse supervision, low salaries, isolation of the hospital, en masse type of care, institutional rigidity, and entrenched personnel—all militate against the young nurse's choosing to work in a public mental hospital. And parents, who often reflect public attitudes toward mental illness, have been slow to encourage the young nurse to consider psychiatric work as a career choice.

Collegiate schools of nursing, which require 4 years of study leading to a baccalaureate degree, supply about 17 per cent of the nation's nurses at this time. Students in these programs also have a course entitled "Nursing in Psychiatry," which is generally 8 to 15 weeks in length. Faculty members employed by the college utilize psychiatric services in the university medical center or accompany the students to a psychiatric hospital for selected clinical experiences. An effort is made to draw on the basic sciences, humanities, and other academic subjects the student has completed prior to this course and to explore theories explaining the pathology the student encounters in her interactions with patients. A typical program includes orientation to the course and clinical facilities, a nurse-patient relationship study and

seminar, and lectures by nurses and faculty from other professional schools, such as the department of psychiatry and school of social work. Discussions and guided readings in behavioral science and psychiatric theories are utilized as these relate to patient behavior and to therapeutic nursing approaches. There is study and participant observation of typical categories of mental illness and of the terminology and concepts that other disciplines use in discussing these entities. Sociology of the mental hospital, legal and community aspects of mental illness and mental health, concepts and techniques of interviewing, and some exposure to interdisciplinary team concepts and functioning are also included. There is discussion of the role of staff nurse, including similarities and differences in the care of patients in psychiatric services as contrasted to other clinical services in the general hospital. There are also field trips to selected community agencies to discuss these resources for help in mental illness and mental retardation.

Collegiate schools have not contributed substantially to the numbers of staff nurses employed in psychiatric settings, but they have provided students immediately ready for graduate study in master's degree programs of psychiatric nursing.

Role in a psychiatric setting. A registered nurse who seeks a staff nurse position in a psychiatric setting expects competent clinical supervision by a qualified psychiatric nurse. Many institutions provide administrative supervisors but do not have qualified psychiatric nurses to whom the novice nurse can turn for review of clinical work and answers to complicated questions relating to daily nursing practices with patients.

A staff nurse usually works in a ward setting in an institution that provides treatment for psychiatric inpatients. Her first task is to guide nonprofessional nursing personnel in giving care, usually bathing, feeding, protection against bodily harm, and the like. The nurse also gives medication, carries out procedures, changes dressings, and the like. The staff nurse is also expected to be a sensitive observer of the interactions that go on between patients and between patients and staff. Since psychiatric patients tend to use patterns of behavior that replicate past experiences and that may reinforce pathology, the staff nurse is expected to observe recurring patterns and to plan and guide sustained nursing interventions that tend to promote favorable change in the patient. The staff nurse is aided in this task by observations of patient-visitor interactions, by recourse to case data, and by discussions with professional staff members who may be providing more direct psychotherapeutic treatment of a particular patient or his family.

The staff nurse also intervenes in various types of emergency situations that arise daily within the treatment milieu. For example, two patients may engage in a heated dispute, often replicating rivalrous situations between siblings that were ineptly handled in

their earlier life situations. She must arbitrate the dispute so that both patients save face and learn something from the incident. Stealing is also a common problem, especially in public mental hospitals; the staff nurse investigates reported incidents primarily by discussion with all patients reportedly involved, with the aim of promoting larger social awareness in these patients. The application of theories of personality development aid the staff nurse in recognizing lacks, gaps, and stalemates in personal development; the nurse provides concerned and competent help in providing useful experiences in the course of daily living on the ward. The staff nurse must be alert to increases in anxiety in particular patients and to its spread in groups of patients. Interventions to forestall panic are used to reduce the growth of more severe pathology.

Many staff nurses also function as recorders or co-leaders in organized group therapy sessions conducted by psychiatric nurses or by other professionals within psychiatric hospitals. Moreover, brief counseling of patients is being recognized as a function of staff nurses, particularly graduates of collegiate schools of nursing.

Where there are psychiatric teams, the nurse provides information to be used in preparing or revising a plan of treatment for each patient. For example, the nurse reports information having to do with medications, eating and sleeping patterns, and the like. She also describes her observations of a particular patient's interactions with others in the ward setting, the inferences she has drawn from patterns of behavior, and the actions taken by nursing personnel in response to these patterns. Furthermore, nursing notes on all patients are written by all nursing personnel; they provide an anecdotal record by which the entire staff can judge variation or change in the daily behavior of patients. The nurse also obtains observations from other team members. These data assist the staff nurse in noting differences in the patient's behavior in relationships with male and female workers, authority figures, peerlike figures, and the like. Such data provide a broader base for revising nursing services for particular patients.

The staff nurse engineers various diversional activities within the ward setting. She cooperates with such departments as occupational and recreational therapy in providing on-the-ward programs and in arranging for patients to work in these departments off the ward. There is a trend toward ward government, remotivation, and informal discussions among groups of patients; nurses sometimes organize these and sometimes are participants when the direction comes from the psychiatrist or other hospital staff member.

The staff nurse serves as a resource person to licensed practical nurses and attendants and gives direction to their work by encouraging review of incidents in which actions have been taken by these

workers. She sometimes conducts discharge conferences with patients, discussing the patient's reactions to going home and his anticipation of community reaction to him as an ex-mental patient. Staff nurses sometimes arrange referrals of patients to public health nursing agencies and to community resources.

In day care and clinic settings, the staff nurse is gradually relinquishing receptionist-type activities for a more direct role in treatment of patients. Particularly in day care settings, nurses are utilizing practices similar to those described for the in-patient unit. In clinics, staff nurses provide brief situational interviewing for selected patients and, particularly those who have had public health nursing experience, make home visits. On these visits, a nurse supervises medications, observes family interactions, and evaluates progress made by the patient. Reports of such home visits serve as a basis for evaluation and change in the clinic treatment plan.

Education of psychiatric nurses. A psychiatric nurse is a registered nurse who has completed a program of study in psychiatric nursing in a university setting and who therefore holds a master's or doctoral degree. Currently in this country, there are perhaps 1,500 such nurses; about 720 of these are employed in psychiatric services; the others are in instructional positions in colleges and universities. There are 33 university graduate programs, and a recent report indicates a trend toward increasing enrollment at the graduate level.

A master's program in psychiatric nursing varies in length from 12 to 19 months, with most of the programs being at least 15 months long. Such programs include advanced clinical training and academic course work in the behavioral sciences, statistics, and research. The graduate student chooses to specialize in psychiatric nursing of adults, of emotionally disturbed children, or of mental retardates. Many of these programs also include course work and practice in teaching and supervision in addition to preparation for clinical specialization in psychiatric nursing.

Psychiatric nurses are being encouraged to pursue studies at the doctoral level. Currently, one university offers the degree of Doctor in Nursing Science. Many universities accept nurses for study in doctor of philosophy or doctor of education programs in any basic science for which the nurse can qualify.

Role. The clinical specialist in psychiatric nursing provides direct nursing services to selected patients in any setting. These services include individual psychotherapy, group psychotherapy, sociological assessment of a milieu such as ward or home, and the more informal interventions described above for the staff nurse. The psychiatric nurse also participates in systematic clinical investigations and studies.

When employed within a hospital, the psychiatric nurse is not usually based in a particular ward; instead, together with other members of the psychiatric

team and frequently after discussion with the clinical director, she selects particular patients and schedules direct work with them. Summaries of the work are filed in the permanent record of the patient. The psychiatric nurse also presents her observations to the clinical staff in such meetings as diagnostic and discharge conferences. Moreover, the psychiatric nurse specialist often meets as a resource person with the ward team to interpret needs of patients with whom she works and to suggest nursing approaches the nursing staff would find useful.

Clinical specialty preparation in psychiatric nursing is being advocated for all teachers and supervisors of psychiatric nursing. Psychiatric nurse leaders believe that it has been demonstrated in the last decade or two that professional nursing can and must contribute direct services to people who are mentally ill or mentally retarded if the need for help of over one million in-patients is to be met through professional services.

Suggested Cross References

The nurse forms a crucial aspect of the psychiatric patient's milieu. For further information regarding

the effects of environment on the course of psychiatric disorders, see Chapter 36 on milieu therapy.
